Abstract

Adjusted for chance measures are widely used to compare partitions/clusterings of the same data set. In particular, the Adjusted Rand Index (ARI) based on pair-counting, and the Adjusted Mutual Information (AMI) based on Shannon information theory are very popular in the clustering community. Nonetheless it is an open problem as to what are the best application scenarios for each measure and guidelines in the literature for their usage are sparse, with the result that users often resort to using both. Generalized Information Theoretic (IT) measures based on the Tsallis entropy have been shown to link pair-counting and Shannon IT measures. In this paper, we aim to bridge the gap between adjustment of measures based on pair-counting and measures based on information theory. We solve the key technical challenge of analytically computing the expected value and variance of generalized IT measures. This allows us to propose adjustments of generalized IT measures, which reduce to well known adjusted clustering comparison measures as special cases. Using the theory of generalized IT measures, we are able to propose the following guidelines for using ARI and AMI as external validation indices: ARI should be used when the reference clustering has large equal sized clusters; AMI should be used when the reference clustering is unbalanced and there exist small clusters.

Keywords: Clustering Comparison, Clustering Validation, Adjustment for Chance, Generalized Information Theoretic Measures, Pair-Counting Measures

1. Introduction

Clustering comparison measures are used to compare partitions/clusterings of the same data set. In the clustering community (Aggarwal and Reddy, 2013), they are extensively used for external validation when the ground truth clustering is available. A family of popular clustering comparison measures are measures based on pair-counting (Albatineh et al., 2006). This category comprises the well known similarity measures Rand Index (RI) (Rand, 1971) and the Jaccard coefficient (J) (Ben-Hur et al., 2001). Recently, information theoretic (IT) measures have been also extensively used to compare partitions (Strehl and Ghosh, 2003; Vinh et al., 2010). Given the variety of different possible measures, it is very challenging to identify the best choice for a particular application scenario (Wu et al., 2009).

The picture becomes even more complex if adjusted for chance measures are also considered. Adjusted for chance measures are widely used external clustering validation techniques
because they improve the interpretability of the results. Indeed, two important properties hold true for adjusted measures: they have constant baseline equal to 0 value when the partitions are random and independent, and they are equal to 1 when the compared partitions are identical. Notable examples are the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) and the Adjusted Mutual Information (AMI) (Vinh et al., 2009). It is common to see published research that validates clustering solutions against a reference ground truth clustering with the ARI or the AMI. Nonetheless there are still open problems: there are no guidelines for their best application scenarios shown in the literature to date and authors often resort to employing them both and leaving the reader to interpret.

Moreover, some clustering comparisons measures are susceptible to selection bias: when selecting the most similar partition to a given ground truth partition, clustering comparison measures are more likely to select partitions with many clusters (Romano et al., 2014). In Romano et al. (2014) it was shown that it is beneficial to perform statistical standardization to IT measures to correct for this bias. In particular, standardized IT measures help in decreasing this bias when the number of objects in the data set is small. Statistical standardization has not been applied to pair-counting measures yet in the literature. We solve this challenge in the current paper, and provide further results about the utility of measure adjustment by standardization.

In this work, we aim to bridge the gap between the adjustment of pair-counting measures and the adjustment of IT measures. In Furuichi (2006) and Simovici (2007) it has been shown that generalized IT measures based on the Tsallis $q$-entropy (Tsallis et al., 2009) are a further generalization of IT measures and some pair-counting measures such as RI. In this paper, we will exploit this useful idea to connect ARI and AMI. Furthermore using the same idea, we can perform statistical adjustment by standardization to a broader class of measures, including pair-counting measures.

A key technical challenge is to analytically compute the expected value and variance for generalized IT measures when the clusterings are random. To solve this problem, we propose a technique applicable to a broader class of measures we name $L_\phi$, which includes generalized IT measures as a special case. This generalizes previous work which provided analytical adjustments for narrower classes: measures based on pair-counting from the family $L$ (Albatineh et al., 2006), and measures based on the Shannon mutual information (Vinh et al., 2009, 2010). Moreover, we define a family of measures $N_\phi$ which generalizes many clustering comparison measures. For measures which belong in this family, the expected value can be analytically approximated when the number of objects is large. Figure 1 depicts the families of measures discussed in this paper. Table 1 summarizes the development of this line of work over the past 30 years and positions our contribution. In summary, we make the following contributions:

- We define families of measures for which the expected value and variance can be computed analytically when the clusterings are random;
- We propose generalized adjusted measures to correct for the baseline property and for selection bias. This captures existing well known measures as special cases;
- We provide insights into the open problem of identifying the best application scenarios for clustering comparison measures, in particular the application scenarios for ARI and AMI.
Adjusting for Chance Clustering Comparison Measures

Figure 1: Families of clustering comparison measures discussed in this paper. We show how to analytically adjust measures in $\mathcal{L}_\phi$ and how to obtain approximations for the family $\mathcal{N}_\phi$.

Table 1: Work on adjusting clustering comparison measures carried out over the past 30 years. Information theoretic measures have been only recently adjusted for chance. In this paper, we bridge the gap between adjustment of pair-counting measures and information theoretic measures.

2. Comparing Partitions

Given two partitions (clusterings) $U$ and $V$ of the same data set of $N$ objects, let $\{u_1, \ldots, u_r\}$ and $\{v_1, \ldots, v_c\}$ be the disjoint sets (clusters) for $U$ and $V$ respectively. Let $|u_i| = a_i$ for $i = 1, \ldots, r$ denote the number of objects in the set $u_i$ and $|v_j| = b_j$ for $j = 1, \ldots, c$ denote the number of objects in $v_j$. Naturally, $\sum_{i=1}^r a_i = \sum_{j=1}^c b_j = N$. The overlap between the two partitions $U$ and $V$ can be represented in matrix form by a $r \times c$ contingency table $\mathcal{M}$ where $n_{ij}$ represents the number of objects in both $u_i$ and $v_j$, i.e. $n_{ij} = |u_i \cap v_j|$. Also, we refer to $a_i = \sum_{j=1}^c n_{ij}$ as the row marginals and to $b_j = \sum_{i=1}^r n_{ij}$ as the column marginals. A contingency table $\mathcal{M}$ is shown in Table 2.

Pair-counting measures between partitions, such as the Rand Index (RI) (Rand, 1971), might be defined using the following quantities: $k_{11}$, the pairs of objects in the same set in both $U$ and $V$; $k_{00}$ the pairs of objects not in the same set in $U$ and not in the same set in $V$; $k_{10}$, the pairs of objects in the same set in $U$ and not in the same set in $V$; and $k_{01}$ the pairs of objects not in the same set in $U$ and in the same set in $V$. All these quantities can
Table 2: $r \times c$ contingency table $\mathcal{M}$ related to two clusterings $U$ and $V$. $a_i = \sum_j n_{ij}$ are the row marginals and $b_j = \sum_i n_{ij}$ are the column marginals.

be computed using the contingency table $\mathcal{M}$, for example:

$$k_{11} = \frac{1}{2} \sum_{i=1}^{r} \sum_{j=1}^{c} n_{ij} (n_{ij} - 1), \quad k_{00} = \frac{1}{2} \left( N^2 + \sum_{i=1}^{r} \sum_{j=1}^{c} n_{ij}^2 - \left( \sum_{i=1}^{r} a_i^2 + \sum_{j=1}^{c} b_j^2 \right) \right)$$  \hspace{1cm} (1)

Using $k_{00}$, $k_{11}$, $k_{10}$, and $k_{01}$ it is possible to compute similarity measures, e.g. RI, or distance measures, e.g. the Mirkin index $\text{MK}(U, V) \triangleq \sum_i a_i^2 + \sum_j b_j^2 - 2 \sum_{i,j} n_{ij}^2$, between partitions (Meilă, 2007):

$$\text{RI}(U, V) \triangleq (k_{11} + k_{00}) / \binom{N}{2}, \quad \text{MK}(U, V) = 2(k_{10} + k_{01}) = N(N-1)(1 - \text{RI}(U, V))$$ \hspace{1cm} (2)

Information theoretic measures are instead defined for random variables but can also be used to compare partitions when we employ the empirical probability distributions associated to $U$, $V$, and the joint partition $(U, V)$. Let $\frac{a_i}{N}$, $\frac{b_j}{N}$, and $\frac{n_{ij}}{N}$ be the probability that an object falls in the set $u_i$, $v_j$, and $u_i \cap v_j$ respectively. We can therefore define the Shannon entropy with natural logarithms for a partition $V$ as follows: $H(V) \triangleq -\sum_j \frac{b_j}{N} \ln \frac{b_j}{N}$. Similarly, we can define the entropy $H(U)$ for the partition $U$, the joint entropy $H(U, V)$ for the joint partition $(U, V)$, and the conditional entropies $H(U|V)$ and $H(V|U)$. Shannon entropy can be used to define the well know Mutual Information (MI) and employ it to compute similarity between partitions $U$ and $V$:

$$\text{MI}(U, V) \triangleq H(U) - H(U|V) = H(V) - H(V|U) = H(U) + H(V) - H(U, V)$$ \hspace{1cm} (3)

On contingency tables, MI is linearly related to $G$-statistics used for likelihood-ratio tests: $G = 2\text{NMI}$. In Meilă (2007), using the Shannon entropy it was shown that the following distance, namely the Variation of Information (VI) is a metric:

$$\text{VI}(U, V) \triangleq 2H(U, V) - H(U) - H(V) = H(U|V) + H(V|U) = H(U) + H(V) - 2\text{MI}(U, V)$$ \hspace{1cm} (4)

Information theoretic measures are extensively used to compare crisp partitions (Strehl and Ghosh, 2003; Vinh et al., 2010). Very recently they have also been used to compare fuzzy partitions (Lei et al., 2014a, 2016).
2.1 Generalized Information Theoretic Measures

Generalized Information Theoretic (IT) measures based on the generalized Tsallis $q$-entropy (Tsallis, 1988) can be defined for random variables (Furuichi, 2006) and also be applied to the task of comparing partitions (Simovici, 2007). Indeed, these measures have also seen recent application in the machine learning community. More specifically, it has been shown that they can act as proper kernels (Martins et al., 2009). Furthermore, empirical studies demonstrated that careful choice of $q$ yields successful results when comparing the similarity between documents (Vila et al., 2011), decision tree induction (Maszczyk and Duch, 2008; Wang et al., 2015), and reverse engineering of biological networks (Lopes et al., 2011). It is important to note that the Tsallis generalized entropy proposed in Havrda and Charvát (1967); Daróczy (1970). Results available in literature about these generalized entropies are equivalently valid for all the proposed versions.

Given $q \in \mathbb{R}^+ - \{1\}$, the generalized Tsallis $q$-entropy for a partition $V$ is defined as follows: $H_q(V) \triangleq \frac{1}{q-1} \left(1 - \sum_j \left(\frac{b_j}{N}\right)^q\right)$. Similarly to the case of Shannon entropy, we have the joint $q$-entropy $H_q(U,V)$ and the conditional $q$-entropies $H_q(U|V)$ and $H_q(V|U)$. Conditional $q$-entropy is computed according to a weighted average parametrized on $q$. More specifically the formula for $H_q(V|U)$ is:

$$H_q(V|U) \triangleq \sum_i \left(\frac{a_i}{N}\right)^q H_q(V|u_i) = \sum_i \left(\frac{a_i}{N}\right)^q \frac{1}{q-1} \left(1 - \sum_j \left(\frac{n_{ij}}{a_i}\right)^q\right) \quad (5)$$

The $q$-entropy reduces to the Shannon entropy computed in nats for $q \to 1$.

In Furuichi (2006), using the fact that $q > 1$ implies $H_q(U) \geq H_q(U|V)$, it is shown that non-negative MI can be naturally generalized with $q$-entropy when $q > 1$:

$$MI_q(U,V) \triangleq H_q(U) - H_q(U|V) = H_q(V) - H_q(V|U) = H_q(U) + H_q(V) - H_q(U,V) \quad (6)$$

However, $q$ values smaller than 1 are allowed if the assumption that $MI_q(U,V)$ is always positive can be dropped. In addition, generalized IT measures can be used to define the generalized Variation of Information distance ($VI_q$) which tends to VI in Eq. (4) when $q \to 1$:

$$VI_q(U,V) \triangleq H_q(U|V) + H_q(V|U) = 2H_q(U,V) - H_q(U) - H_q(V) = H_q(U) + H_q(V) - 2MI_q(U,V) \quad (7)$$

In Simovici (2007) it was shown that $VI_q$ is a proper metric and interesting links were identified between measures for comparing partitions $U$ and $V$. We state these links in Proposition 1 given that they set the fundamental motivation of our paper:

**Proposition 1 (Simovici, 2007)** When $q = 2$ the generalized variation of information, the Mirkin index, and the Rand index are linearly related: $VI_2(U,V) = \frac{1}{N^2} MK(U,V) = \frac{N-1}{N} (1 - RI(U,V))$.

Generalized IT measures are not only a generalization of IT measures in the Shannon sense but also a generalization of pair-counting measures for particular values of $q$. Note that in literature there exist another well know generalization of entropy: the Renyi entropy (Renyi,
This entropy is again parametrized on a real number $q$ and is defined as follows: $R_q(V) \triangleq \frac{1}{1-q} \ln \left( \sum_j \left( \frac{b_j}{N} \right)^q \right)$. Because of the use of the logarithm for any value of $q$, the Renyi entropy does enable the generalization of pair-counting measures when $q = 2$. Therefore, in this paper we make use of generalized IT measures based on the Tsallis entropy.

2.2 Normalized Generalized IT Measures

To allow a more interpretable range of variation, a clustering similarity measure should be normalized: it should achieve its maximum at 1 when $U = V$. An upper bound to the generalized mutual information $\text{MI}_q$ is used to obtained a normalized measure. $\text{MI}_q$ can take different possible upper bounds (Furuichi, 2006). Here, we choose to derive another possible upper bound using Eq. (7) when we use the minimum value of $\text{VI}_q = 0$: $\max \text{MI}_q = \frac{1}{2}(H_q(U) + H_q(V))$. This upper bound is valid for any $q \in \mathbb{R}^+ - \{1\}$ and allows us to link different existing measures as we will show in the next sections of the paper. The Normalized Mutual Information with $q$-entropy ($\text{NMI}_q$) is defined as follows:

$$\text{NMI}_q(U, V) \triangleq \frac{\text{MI}_q(U, V)}{\max \text{MI}_q(U, V)} = \frac{\text{MI}_q(U, V)}{\frac{1}{2}(H_q(U) + H_q(V))} = \frac{H_q(U) + H_q(V) - H_q(U, V)}{\frac{1}{2}(H_q(U) + H_q(V))}$$ (8)

Even if $\text{NMI}_q(U, V)$ achieves its maximum 1 when the partitions $U$ and $V$ are identical, $\text{NMI}_q(U, V)$ is not a suitable clustering comparison measure. Indeed, it does not show constant baseline value equal to 0 when partitions are random. We explore this through an experiment. Given a dataset of $N = 100$ objects, we randomly generate uniform partitions $U$ with $r = 2, 4, 6, 8, 10$ sets and $V$ with $c = 6$ sets independently of each others. The average value of $\text{NMI}_q$ over 1,000 simulations for different values of $q$ is shown in Figure 2. It is reasonable to expect that when the partitions are independent, the average value of $\text{NMI}_q$ is constant irrespectively of the number of sets $r$ of the partition $U$. This is not the case. This behavior is unintuitive and misleading when comparing partitions.

![Figure 2: The baseline value of NMIq(U, V) between independent random partitions U and V. Despite the partitions are random, the baseline of NMIq is not constant and depends on the number of sets of the partitions.](image)
Proposition 1, this strategy also allows us to generalize adjusted for chance pair-counting and Shannon IT measures.

3. Baseline Adjustment

In order to adjust the baseline of a similarity measure $S(U, V)$, we have to compute its expected value under the null hypothesis of independent random partitions $U$ and $V$. We adopt the assumption of randomness used to adjust RI (Hubert and Arabie, 1985) and the Shannon MI (Vinh et al., 2009). This is formalized as follows:

**Definition 1 (Random partitions)** The partitions $U$ and $V$ are generated independently and at random fixing the number of objects $N$ and the marginals $a_i$ and $b_j$.

This is also denoted as the permutation or the hypergeometric model of randomness. We are able to compute the exact expected value for a similarity measure in the family $L_\phi$:

**Definition 2** Let $L_\phi$ be the family of similarity measures $S(U, V) = \alpha + \beta \sum_{ij} \phi_{ij}(n_{ij})$ where $\alpha$ and $\beta$ do not depend on the entries $n_{ij}$ of the contingency table $M$ and $\phi_{ij}(\cdot)$ are bounded real functions.

Intuitively, $L_\phi$ represents the class of measures that can be written as a linear combination of $\phi_{ij}(n_{ij})$. A measure between partitions uniquely determines $\alpha$, $\beta$, and $\phi_{ij}$. However, not every choice of $\alpha$, $\beta$, and $\phi_{ij}$ yields a meaningful similarity measure. $L_\phi$ is a superset of the set $L$ defined in Albatineh et al. (2006) as the family of measures $S(U, V) = \alpha + \beta \sum_{ij} n_{ij}^2$, i.e. $S \in L$ are special cases of measures in $L_\phi$ with $\phi_{ij}(\cdot) = (\cdot)^2$. Figure 1 shows a diagram of the similarity measures discussed in Section 2.1 and their relationships.

**Lemma 1** If $S(U, V) \in L_\phi$, when partitions $U$ and $V$ are random:

$$E[S(U, V)] = \alpha + \beta \sum_{ij} E[\phi_{ij}(n_{ij})] \quad \text{where} \quad E[\phi_{ij}(n_{ij})] \quad \text{(9)}$$

$$\min(0, a_i+b_j-N) \Phi \left(n_{ij} \left( \frac{a_i! b_j! (N-a_i)! (N-b_j)!}{N! n_{ij}! (a_i-n_{ij})! (b_j-n_{ij})! (N-a_i-b_j+n_{ij})!} \right) \right) \quad \text{(10)}$$

Lemma 1 extends the results in Albatineh and Niewiadomska-Bugaj (2011) showing exact computation of the expected value of measures in the family $L$. Given that generalized IT measures belong in $L_\phi$ we can employ this result to adjust them.

3.1 Baseline Adjustment for Generalized IT measures

Using Lemma 1 it is possible to compute the exact expected value of $H_q(U, V)$, $\mathrm{VI}_q(U, V)$ and $\mathrm{MI}_q(U, V)$:

**Theorem 1** When the partitions $U$ and $V$ are random:

i) $E[H_q(U, V)] = \frac{1}{q-1} \left(1 - \frac{1}{N^q} \sum_{ij} E[n_{ij}^q] \right)$ with $E[n_{ij}^q]$ from Eq. (10) with $\phi_{ij}(n_{ij}) = n_{ij}^q$;

ii) $E[\mathrm{MI}_q(U, V)] = H_q(U) + H_q(V) - E[H_q(U, V)]$;
iii) \( E[\text{VI}_q(U, V)] = 2E[H_q(U, V)] - H_q(U) - H_q(V) \).

It is worth noting that this approach is valid for any \( q \in \mathbb{R}^+ - \{1\} \). We can use these expected values to adjust for baseline generalized IT measures. We use the method proposed in Hubert and Arabie (1985) to adjust similarity measures, such as \( \text{MI}_q \), and distance measures, such as \( \text{VI}_q \):

\[
\text{AMI}_q \triangleq \frac{\text{MI}_q - E[\text{MI}_q]}{\max \text{MI}_q - E[\text{MI}_q]} \quad \text{AVI}_q \triangleq \frac{E[\text{VI}_q] - \text{VI}_q}{E[\text{VI}_q] - \min \text{VI}_q}
\]

\( \text{VI}_q \) is a distance measure, thus \( \min \text{VI}_q = 0 \). For \( \text{MI}_q \) we use the upper bound \( \max \text{MI}_q = \frac{1}{2}(H_q(U) + H_q(V)) \) as for \( \text{NMI}_q \) in Eq. (8). An exhaustive list of adjusted versions of Shannon MI can be found in Vinh et al. (2010), when the upper bound \( \frac{1}{2}(H_q(U) + H_q(V)) \) is used the authors named the adjusted MI as \( \text{AMI}_{\text{sum}} \).

It is important to note that this type of adjustment turns distance measures into similarity measures, i.e., \( \text{AVI}_q \) is a similarity measure. It is also possible to maintain both the distance properties and the baseline adjustment using \( \text{NVI}_q \triangleq \text{VI}_q / E[\text{VI}_q] \) which can be seen as a normalization of \( \text{VI}_q \) with the stochastic upper bound \( E[\text{VI}_q] \) (Vinh et al., 2009). It is also easy to see that \( \text{AVI}_q = 1 - \text{NVI}_q \). The adjustments in Eq. (11) also enable the measures to be normalized. \( \text{AMI}_q \) and \( \text{AVI}_q \) achieve their maximum at 1 when \( U = V \) and their minimum is 0 when \( U \) and \( V \) are random partitions.

According to the chosen upper bound for \( \text{MI}_q \), we obtain the nice analytical form shown in Theorem 2. Our adjusted measures quantify the discrepancy between the values of the actual contingency table and their expected value in relation to the maximum discrepancy possible, i.e. the denominator in Eq. (12). It is also easy to see that all measures in \( \mathcal{L}_\phi \) resemble this form when adjusted.

**Theorem 2** Using \( E[n_{ij}^q] \) in Eq. (10) with \( \phi_{ij}(n_{ij}) = n_{ij}^q \), the adjustments for chance for \( \text{MI}_q(U, V) \) and \( \text{VI}_q(U, V) \) are:

\[
\text{AMI}_q(U, V) = \text{AVI}_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\frac{1}{2}(\sum_i a_i^q + \sum_j b_j^q) - \sum_{ij} E[n_{ij}^q]}
\]

From now on we only discuss \( \text{AMI}_q \), given that it is identical to \( \text{AVI}_q \). There are notable special cases for our proposed adjusted generalized IT measures. In particular, the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985) is equal to \( \text{AMI}_2 \). ARI is a classic measure, heavily used for validation in social sciences and the most popular clustering validity index.

**Corollary 1** It holds true that:

i) \( \lim_{q \to 1} \text{AMI}_q = \lim_{q \to 1} \text{AVI}_q = \text{AMI} = \text{AVI} \) with Shannon entropy;

ii) \( \text{AMI}_2 = \text{AVI}_2 = \text{ARI} \).

Therefore, using the permutation model we can perform baseline adjustment to generalized IT measures. Our generalized adjusted IT measures are a further generalization of particular well known adjusted measures such as AMI and ARI. It is worth noting, that ARI is equivalent to other known measures for comparing partitions (Albatineh et al., 2006).
Furthermore, there is also a strong connection between ARI and Cohen’s $\kappa$ statistics used to quantify inter-rater agreement (Warrens, 2008). As final remark, we point out that our baseline adjustments can also be seen as statistical corrections for generalized information theoretic measures. It is indeed well known that information theoretic measures are severely biased when plug-in estimators are used, and many have worked on correcting this bias for decades: there exist in literature frequentist approaches (Paninski, 2003) as well as Bayesian approaches (Archer et al., 2013; Cerquetti, 2014) to reduce bias. In this section, we discussed an adjustment to obtain exact bias correction in particular when $U$ and $V$ are independent.

**Computational complexity:** The computational complexity of $\text{AMI}_q$ in Eq. (12) is dominated by the computation of the sum of the expected value of each cell.

**Proposition 2** The computational complexity of $\text{AMI}_q$ is $O(N \cdot \max\{r, c\})$.

If all the possible contingency tables $\mathcal{M}$ obtained by permutations were generated, the computational complexity of the exact expected value would be $O(N!)$. However, this can be dramatically reduced using properties of the expected value.

### 3.2 Experiments on Measure Baseline

Here we show that our adjusted generalized IT measures have a baseline value of 0 when comparing random partitions $U$ and $V$. In Figure 3 we show the behavior of $\text{AMI}_q$, ARI, and AMI on the same experiment proposed in Section 2.2. They are all close to 0 with negligible variation when the partitions are random and independent. Moreover, it is interesting to see the equivalence of $\text{AMI}_2$ and ARI. On the other hand, the equivalence of $\text{AMI}_q$ and AMI with Shannon entropy is obtained only at the limit $q \rightarrow 1$.

![Figure 3: Baseline value of adjusted clustering comparison measures between two random partitions. When varying the number of sets for the random partition $U$, the value of $\text{AMI}_q(U, V)$ is always very close to 0 with negligible variation for any $q$.](image)

We also point out that $\text{NMI}_q$ does not show constant baseline when the relative size of the sets in $U$ varies when $U$ and $V$ are random. In Figure 4, we generate random partitions $V$ with $c = 6$ sets on $N = 100$ points, and random binary partitions $U$ independently. $\text{NMI}_q(U, V)$ shows different behavior at the variation of the relative size of the biggest set.
in $U$. This is unintuitive given that the partitions $U$ and $V$ are random and independent. We obtain the desired property of a baseline value of 0 with $\text{AMI}_q$.

Figure 4: The left panel shows the baseline value of $\text{NMI}_q(U, V)$ between the random partitions $U$ and $V$ at the variation of the size of the sets in $U$. The right panel shows the baseline value of adjusted clustering comparison measures. When varying the relative size of one cluster for the random partition $U$, the value of $\text{AMI}_q(U, V)$ is always very close to 0 with negligible variation for any $q$.

3.3 Large Number of Objects

In this section, we introduce a very general family of measures which includes $\mathcal{L}_\phi$. For measures belonging to this family, it is possible to find an approximation of their expected value when the number of objects $N$ is large. This allows us to identify approximations for the expected value of measures in $\mathcal{L}_\phi$ as well as for measures not in $\mathcal{L}_\phi$, such as the Jaccard coefficient as shown in Figure 1.

Let $\mathcal{N}_\phi$ be the family of measures which are non-linear combinations of $\phi_{ij}(n_{ij})$:

**Definition 3** Let $\mathcal{N}_\phi$ be the family of similarity measures $S(U, V) = \phi(n_{11}/N, \ldots, n_{ij}/N, \ldots, n_{rc}/N)$ where $\phi$ is a bounded real function as $N$ reaches infinity.

Note that $\mathcal{N}_\phi$ is a generalization of $\mathcal{L}_\phi$. At the limit of large number of objects $N$, it is possible to compute the expected value of measures in $\mathcal{N}_\phi$ under random partitions $U$ and $V$ using only the marginals of the contingency table $\mathcal{M}$:

**Lemma 2** If $S(U, V) \in \mathcal{N}_\phi$, then $\lim_{N \to +\infty} E[S(U, V)] = \phi\left( \frac{a_1}{N}, \frac{b_1}{N}, \ldots, \frac{a_j}{N}, \frac{b_j}{N}, \ldots, \frac{a_r}{N}, \frac{b_c}{N} \right)$.

In Morey and Agresti (1984) the expected value of the RI was computed using an approximated value based on the multinomial distribution. It turns out this approximated value is equal to what we obtain for RI using Lemma 2. The authors of Albatineh et al. (2006) noticed that the difference between the approximation and the expected value obtained with the hypergeometric model is small on empirical experiments when $N$ is large. We point out that this is a natural consequence of Lemma 2 given that $\text{RI} \in \mathcal{L}_\phi \subseteq \mathcal{N}_\phi$. Moreover, the multinomial distribution was also used to compute the expected value of the Jaccard coefficient ($J$) in Albatineh and Niewiadomska-Bugaj (2011), obtaining good results on empirical experiments with many objects. Again, this is a natural consequence of Lemma 2.
given that \( J \in \mathcal{N}_\phi \) but \( J \notin \mathcal{L}_\phi \). Indeed, the Jaccard coefficient does not allow analytical adjustment using the hypergeometric model but it allows an approximation using Lemma 2.

Generalized IT measures belong in \( \mathcal{L}_\phi \subseteq \mathcal{N}_\phi \). Therefore we can employ Lemma 2. When the number of objects is large, the expected value under random partitions \( U \) and \( V \) of \( H_q(U, V) \), \( \text{MI}_q(U, V) \), and \( \text{VL}_q(U, V) \) in Theorem 1 depends only on the entropy of the partitions \( U \) and \( V \), i.e., just the marginals of the contingency table must be taken into account:

**Theorem 3** It holds true that:

1. \( \lim_{N \to +\infty} E[H_q(U, V)] = H_q(U) + H_q(V) - (q - 1)H_q(U)H_q(V) \);
2. \( \lim_{N \to +\infty} E[\text{MI}_q(U, V)] = (q - 1)H_q(U)H_q(V) \);
3. \( \lim_{N \to +\infty} E[\text{VL}_q(U, V)] = H_q(U) + H_q(V) - 2(q - 1)H_q(U)H_q(V) \).

Result i) recalls the property of non-additivity that holds true for random variables (Furuichi, 2006). Figure 5 shows the behavior of \( E[H_q(U, V)] \) when the partitions \( U \) and \( V \) are generated uniformly at random. \( V \) has \( c = 6 \) sets and \( U \) has \( r \) sets. In this case, \( H_q(U) + H_q(V) - (q - 1)H_q(U)H_q(V) \) appears to be a good approximation already for \( N = 1000 \). In particular, the approximation is good when the number of objects \( N \) is big with regards to the number of cells of the contingency table in Table 2: i.e., when \( \frac{N}{rc} \) is large enough.

![Approximation on smaller sample size](image1)

![Approximation on bigger sample size](image2)

Figure 5: The left panel shows the average value of \( E[H_q(U, V)] \) between random partitions \( U \) and \( V \) when they are induced on \( N = 50 \) objects. The right panel shows results for \( N = 1000 \) objects. \( E[H_q(U, V)] \) are plotted using a solid line and their limit value \( H_q(U) + H_q(V) - (q - 1)H_q(U)H_q(V) \) is plotted using a dashed line. The solid line coincides approximately with the dashed one in 4(b) when \( N = 1000 \). The limit value is a good approximation for \( E[H_q(U, V)] \) when \( \frac{N}{rc} \) is large enough.

From point ii) follows the result proved in Vinh et al. (2010) to connect the adjusted mutual information to the widely used Normalized Mutual Information (NMI) based on Shannon entropy (Strehl and Ghosh, 2003):

**Theorem 4** (Vinh et al., 2010) It holds true that:

\[
\lim_{N \to +\infty} \text{AMI}(U, V) = \text{NMI}(U, V)
\]
NMI is easier to compute than AMI and it is less prone to computer precision errors. The analysis provided in this session aims at broadening the possible clustering comparison measures that can be adjusted: as long as a measure belongs in $\mathcal{N}_\phi$, its expected value at large $N$ can be computed and thus it can be adjusted. Moreover, we saw that adjusted measures in $\mathcal{L}_\phi \subseteq \mathcal{N}_\phi$ have simpler formulas at large $N$. The adjustments at large $N$ are faster to compute and less prone to computer precision errors.

In the next section we put forward a theoretical analysis on the best choice between AMI and ARI when validating clustering solutions. Moreover being NMI equal to AMI at large $N$, the next section helps also to understand when to use either NMI or ARI.

4. Application Scenarios for AMI$_q$

In this section we aim to answer to the question: Given a reference ground truth clustering $V$, which is the best choice for $q$ in AMI$_q(U, V)$ to validate the clustering solution $U$? By answering this question, we implicitly identify the application scenarios for ARI and AMI given the results in Corollary 1. This is particularly important for external clustering validation. Nonetheless, there are a number of other applications where the task is to find the most similar partition to a reference ground truth partition: e.g., categorical feature selection (Vinh et al., 2014), decision tree induction (Criminisi et al., 2012), generation of alternative or multi-view clusterings (Müller et al., 2013), or the exploration of the clustering space with the Meta-Clustering algorithm (Caruana et al., 2006; Lei et al., 2014b) to list a few.

Different values for $q$ in AMI$_q$ yield to different biases. The source of these biases can be identified by analyzing the properties of the $q$-entropy. In Figure 6 we show the $q$-entropy for a binary partition at the variation of the relative size $p$ of one cluster. This can be analytically computed: $H_q(p) = \frac{1}{q-1}(1 - p^q - (1 - p)^q)$. The range of variation for $H_q(p)$ is much bigger if $q$ is small. More specifically when $q$ is small, the difference in entropy between an unbalanced partition and a balanced partition is big.

Let us focus on an example. Let $V$ be a reference clustering with 3 clusters of size 50 each, and let $U_1$ and $U_2$ be two clustering solutions with the same number of clusters and same cluster sizes. The contingency tables for $U_1$ and $U_2$ are shown on Figure 7. Given that both contingency tables have the same marginals, the only difference between AMI$_q(U_1, V)$ and AMI$_q(U_2, V)$ according to Eq. (11) lies in MI$_q$. Given that both solutions $U_1$ and $U_2$.
Adjusting for Chance Clustering Comparison Measures

Figure 7: Ground truth clustering $V$ compared in turn to the clustering solutions $U_1$ and $U_2$. $\text{AMI}_q$ with small $q$ prefers the solution $U_1$ because there exists one pure cluster: i.e., there is one cluster which contains elements from only one cluster in the reference clustering $V$.

are compared against $V$, the only term that varies in $\text{MI}_q(U,V) = H_q(V) - H_q(V|U)$ is $H_q(V|U)$. In order to identify the clustering solution that maximizes $\text{AMI}_q$ we have to analyze the solution that decreases $H_q(V|U)$ the most. $H_q(V|U)$ is a weighted average of the entropies $H_q(V|u_i)$ computed on the rows of the contingency table as shown in Eq. (5), and this is sensitive to values equal to 0. Given the bigger range of variation of $H_q$ for small $q$, small $q$ implies higher sensitivity to row entropies of 0. Therefore, small values of $q$ tend to decrease $H_q(V|U)$ much more if the clusters in the solution $U$ are pure: i.e., clusters contain elements from only one cluster in the reference clustering $V$. In other words, $\text{AMI}_q$ with small $q$ prefers pure clusters in the clustering solution.

When the marginals in the contingency tables for two solutions are different, another important factor in the computation of $\text{AMI}_q$ is the normalization coefficient $\frac{1}{2}(H_q(U) + H_q(V))$. Balanced solutions $U$ will be penalized more by $\text{AMI}_q$ when $q$ is small. Therefore, $\text{AMI}_q$ with small $q$ prefers unbalanced clustering solutions. To summarize, $\text{AMI}_q$ with small $q$ such as $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ with Shannon entropy:

- Is biased towards pure clusters in the clustering solutions;
- Prefers unbalanced clustering solutions.

By contrary, $\text{AMI}_q$ with bigger $q$ such as $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$:

- Is less biased towards pure clusters in the clustering solution;
- Prefers balanced clustering solutions.

Given a reference clustering $V$, these biases can guide the choice of $q$ in $\text{AMI}_q$ to identify more suitable clustering solutions.

4.1 Use $\text{AMI}_q$ with small $q$ such as $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ when the reference clustering is unbalanced and there exist small clusters

If the reference cluster $V$ is unbalanced and presents small clusters, $\text{AMI}_q$ with small $q$ might prefer more appropriate clustering solutions $U$. For example, in Figure 8 we show two contingency tables associated to two clustering solutions $U_1$ and $U_2$ for the reference
clustering $V$ with 4 clusters of size $[10, 10, 10, 70]$ respectively. When there exist small clusters in the reference $V$ their identification has to be precise in the clustering solution. The solution $U_1$ looks arguably better than $U_2$ because it shows many pure clusters. In this scenario we advise the use of $\text{AMI}_{0.5}$ or $\text{AMI}_1 = \text{AMI}$ with Shannon entropy because it gives more weight to the clustering solution $U_1$.

If the number of objects $N$ is large, AMI is equivalent to NMI according to Theorem 4. Therefore, when the reference clustering is unbalanced, there exist small clusters, and $N$ is large, it is advisable to use NMI rather than ARI.

4.2 Use $\text{AMI}_q$ with big $q$ such as $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$ when the reference clustering has big equal sized clusters

If $V$ is a reference clustering with big equal size clusters it is less crucial to have precise clusters in the solution. Indeed, precise clusters in the solution penalize the recall of clusters from the reference. In this case, $\text{AMI}_q$ with bigger $q$ might prefer more appropriate solutions. In Figure 9 we show two clustering solutions $U_1$ and $U_2$ for the reference clustering $V$ with 4 equal size clusters of size 25. The solution $U_2$ looks better than $U_1$ because each of its clusters identifies more elements from particular clusters in the reference. Moreover, $U_2$ has to be preferred to $U_1$ because it consists in 4 equal sized clusters as the reference clustering $V$ consists in equal sized clusters. In this scenario we advise the use of $\text{AMI}_{2.5}$ or $\text{AMI}_2 = \text{ARI}$ because it gives more importance to the solution $U_2$.

If the number of objects $N$ is large, AMI is equivalent to NMI according to Theorem 4. Therefore, when the reference clustering is balanced with big equal sized clusters and $N$ is large, it is advisable to use ARI rather than NMI.

5. Standardization of Clustering Comparison Measures

The selection of the most similar partition $U$ to a reference partition $V$ is biased according to the chosen similarity measure, the number of sets $r$ in $U$, and their relative size.
Adjusting for Chance Clustering Comparison Measures

Figure 9: Ground truth clustering $V$ compared in turn to the clustering solutions $U_1$ and $U_2$. $V$ shows equal size clusters. $U_2$ appears to be a better solution than $U_1$ because its clusters are more balanced in size than the clusters in $U_1$. When the reference clustering has big equal sized clusters their precise identification is less crucial. AMI with big $q$ prefers the solution $U_2$ because it is less biased to pure clusters in the solution. In this scenario we advise the use of AMI$_{2.5}$ or AMI$_2 = ARI$.

This phenomena is known as selection bias and it has been extensively studied in decision trees (White and Liu, 1994). Researchers in this area agree that in order to achieve unbiased selection of partitions, distribution properties of similarity measures have to be taken into account (Dobra and Gehrke, 2001; Shih, 2004; Hothorn et al., 2006). Using the permutation model, we proposed in Romano et al. (2014) to analytically standardize the Shannon MI by subtraction of its expected value and division by its standard deviation. In this section, we discuss how to achieve analytical standardization of measures $S \in \mathcal{L}_\phi$.

In order to standardize a measure, we must analytically compute its variance:

**Lemma 3** If $S(U,V) \in \mathcal{L}_\phi$, when partitions $U$ and $V$ are random:

$$\text{Var}(S(U,V)) = \beta^2 \left( E \left[ \sum_{ij} \phi_{ij}(n_{ij})^2 \right] - \left( \sum_{ij} E[\phi_{ij}(n_{ij})] \right)^2 \right),$$

where

$$E \left[ \left( \sum_{ij} \phi_{ij}(n_{ij}) \right)^2 \right]$$

is equal to

$$\sum_{ij} \sum_{n_{ij}} \phi(n_{ij})P(n_{ij}) \cdot \left[ \phi_{ij}(n_{ij}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j}} \phi_{i'j}(\tilde{n}_{i'j})P(\tilde{n}_{i'j}) + \sum_{j' \neq j} \sum_{\tilde{n}_{ij'j'}} \phi_{ij'j'}(\tilde{n}_{ij'j'})P(\tilde{n}_{ij'j'}) \right]$$

(13)

with $n_{ij} \sim \text{Hyp}(a_i, b_j, N)$, $\tilde{n}_{i'j} \sim \text{Hyp}(b_j - n_{ij}, a'_j, N - a_i)$, $\tilde{n}_{ij'j} \sim \text{Hyp}(a_i - n_{ij}, b'_j, N - b_j)$, $\tilde{n}_{ij'j'} \sim \text{Hyp}(a'_j, b'_j - n_{ij'}, N - a_i)$. hypergeometric random variables.

We can use the expected value to standardize measures $S \in \mathcal{L}_\phi$, such as generalized IT measures.
5.1 Standardization of Generalized IT Measures

The variance under the permutation model of generalized IT measures is:

**Theorem 5** Using Eqs. (10) and (13) with \( \phi_{ij}(\cdot) = (\cdot)^q \), when the partitions \( U \) and \( V \) are random:

i) \( \text{Var}(H_q(U, V)) = \frac{1}{(q-1)N^2} \left( E\left[ (\sum_{ij} n_{ij}^q)^2 \right] - (\sum_{ij} E[n_{ij}^q])^2 \right) \);

ii) \( \text{Var}(MI_q(U, V)) = \text{Var}(H_q(U, V)) \)

iii) \( \text{Var}(VI_q(U, V)) = 4\text{Var}(H_q(U, V)) \)

We define the standardized version of the similarity measure \( MI_q \) (SMI\(_q\)), and the standardized version of the distance measure \( VI_q \) (SVI\(_q\)) as follows:

\[
\text{SMI}_q(U, V) = \frac{\text{MI}_q(U, V) - E[\text{MI}_q]}{\sqrt{\text{Var}(\text{MI}_q)}}, \quad \text{SVI}_q(U, V) = \frac{E[\text{VI}_q] - \text{VI}_q}{\sqrt{\text{Var}(\text{VI}_q)}}\
\]  

(14)

As for the case of AMI\(_q\) and AVI\(_q\), it turns out that SMI\(_q\) is equal to SVI\(_q\):

**Theorem 6** Using Eqs. (10) and (13) with \( \phi_{ij}(\cdot) = (\cdot)^q \), the standardized \( MI_q(U, V) \) and the standardized \( VI_q(U, V) \) are:

\[
\text{SMI}_q(U, V) = \text{SVI}_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (\sum_{ij} E[n_{ij}^q])^2}}\]

(15)

This formula shows that we are interested in maximizing the difference between the sum of the cells of the actual contingency table and the sum of the expected cells under randomness. Standardized measures differ from their adjusted counterpart because of the denominator, i.e. the standard deviation of the sums of the cells. Indeed, SMI\(_q\) and SVI\(_q\) measure the number of standard deviations \( MI_q \) and \( VI_q \) are from their mean.

There are some notable special cases for particular choices of \( q \). Indeed, our generalized standardization of IT measures allows us to generalize also the standardization of pair-counting measures such as the Rand index. To see this, let us define the Standardized Rand Index (SRI): \( \text{SRI}_q \triangleq \text{RI} - E[\text{RI}] \frac{E[G] - E[\text{RI}]}{\sqrt{\text{Var}(\text{RI})}} \) and recall that the standardized \( G \)-statistic is defined as \( SG \triangleq \frac{G - E[G]}{\sqrt{\text{Var}(G)}} \) (Romano et al., 2014):

**Corollary 2** It holds true that:

i) \( \lim_{q \to 1} \text{SMI}_q = \lim_{q \to 1} \text{SVI}_q = \text{SMI} = \text{SVI} = SG \) with Shannon entropy;

ii) \( \text{SMI}_2 = \text{SVI}_2 = \text{SRI} \).

**Computational complexity:** The computational complexity of SMI\(_q\) is dominated by computation of the second moment of the sum of the cells defined in Eq. (13):

**Proposition 3** The computational complexity of SMI\(_q\) is \( O(N^3c \cdot \max \{c, r\}) \).

Note that the complexity is quadratic in \( c \) and linear in \( r \). This happens because of the way we decided to condition the probabilities in Eq. (13) in the proof of Lemma 3. With different conditions, it is possible to obtain a formula symmetric to Eq. (13) with complexity \( O(N^3r \cdot \max \{r, c\}) \) (Romano et al., 2014).
Statistical inference: All IT measures computed on partitions can be seen as estimators of their true value computed using the random variables associated to the partitions $U$ and $V$. Therefore, $\text{SMI}_q$ can be used as non-parametric independence test for $\text{MI}_q$. We formalize this with the following proposition:

**Proposition 4** The $p$-value associated to the test for independence between $U$ and $V$ using $\text{MI}_q(U, V)$ is smaller than: $$\frac{1}{1+(\text{SMI}_q(U, V))^2}.$$ 

For example, if $\text{SMI}_q$ is equal to 4.46 the associated $p$-value is smaller than 0.05. Neural time series data is often analyzed making use of the Shannon MI (e.g. see Chapter 29 in Cohen (2014)). It is common practice to test the independence of two time series by computing $\text{SMI}$ via Monte Carlo permutations, sampling from the space of $N!$ cardinality. Our $\text{SMI}_q$ can be effectively and efficiently used in this application because it is exact and obtains $O(N^3r \cdot \max\{r, c\})$ complexity.

### 5.2 Experiments on Selection Bias

In this section, we evaluate the performance of standardized measures on selection bias correction when partitions $U$ are generated at random and independently from the reference partition $V$. This hypothesis has been employed in previous published research to study selection bias (White and Liu, 1994; Frank and Witten, 1998; Dobra and Gehrke, 2001; Shih, 2004; Hothorn et al., 2006; Romano et al., 2014). In particular, we experimentally demonstrate that $\text{NMI}_q$ is biased towards the selection of partitions $U$ with more clusters at any $q$. Therefore, in this scenario it is beneficial to perform standardization. Mind though that the choice of whether performing standardization or not is application dependent (Romano et al., 2015). For example, it has been argued that in some cases the selection of clustering solutions should be biased towards clusterings with the same number of clusters as in the reference (Amelio and Pizzuti, 2015). In this section we aim to show the effects of selection bias when clusterings are independent and that standardization helps in reducing it. Moreover, we will see in Section 5.3 that it is particularly important to correct for selection bias when the number of objects $N$ is small.

Given a reference partition $V$ on $N = 100$ objects with $c = 4$ sets, we generate a pool of random partitions $U$ with $r$ ranging from 2 to 10 sets. Then, we use $\text{NMI}_q(U, V)$ to select the closest partition to the reference $V$. The plot at the bottom of Figure 10 shows the probability of selection of a partition $U$ with $r$ sets using $\text{NMI}_q$ computed on 5000 simulations. We do not expect any partition to be the best given that they are all generated at random: i.e., the plot is expected to be flat if a measure is unbiased. Nonetheless, we see that there is a clear bias towards partitions with 10 sets if we use $\text{NMI}_q$ with $q$ respectively equal to 1.001, 2, or 3. We can see that the use of the adjusted measures such as $\text{AMI}_q$ helps in decreasing this bias, in particular when $q = 2$. On this experiment when $q = 2$, baseline adjustment seems to be effective in decreasing the selection bias because the variance of $\text{AMI}_2 = \text{ARI}$ is almost constant. However for all $q$, using $\text{SMI}_q$ we obtain close to uniform probability of selection of each random partition $U$. 

17
5.3 Large Number of Objects

It is likely to expect that the variance of generalized IT measures decreases when partitions are generated on a large number of objects $N$. Here we prove a general result about measures of the family $\mathcal{N}_\phi$.

Lemma 4 If $S(U,V) \in \mathcal{N}_\phi$, then $\lim_{N \to +\infty} \text{Var}(S(U,V)) = 0$.

Given that generalized IT measures belong in the family $\mathcal{N}_\phi$, we can prove the following:

Theorem 7 It holds true that:

$$\lim_{N \to +\infty} \text{Var}(H_q(U,V)) = \lim_{N \to +\infty} \text{Var}(M_q(U,V)) = \lim_{N \to +\infty} \text{Var}(V_q(U,V)) = 0$$

Therefore, $SMI_q$ attains very large values when $N$ is large. In practice of course, $N$ is finite, so the use of $SMI_q$ is beneficial. However, it is less important to correct for selection bias if the number of objects $N$ is big with regards to the number of cells in the contingency table in Table 2: i.e., when $\frac{N}{r \cdot c}$ is large. Indeed, when the number of objects is large $AMI_q$ might be sufficient to avoid selection bias and any test for independence between partitions has high power. In this scenario, $SMI_q$ is not needed and $AMI_q$ might be preferred as it can be computed more efficiently.

6. Conclusion

In this paper, we computed the exact expected value and variance of measures of the family $\mathcal{L}_\phi$, which contains generalized IT measures. We also showed how the expected value for measures $S \in \mathcal{N}_\phi$ can be computed for large $N$. Using these statistics, we proposed $AMI_q$ and $SMI_q$ to adjust generalized IT measures both for baseline and for selection bias. $AMI_q$ is a further generalization of well known measures for clustering comparisons such as ARI and AMI. This analysis allowed us to provide guidelines for their best application in different scenarios. In particular ARI might be used as external validation index when the reference
clustering shows big equal sized clusters. AMI can be used when the reference clustering is unbalanced and there exist small clusters. The standardized SMI can instead be used to correct for selection bias among many possible candidate clustering solutions when the number of objects is small. Furthermore, it can also be used to test the independence between two partitions. All code has been made available online\(^1\).

Appendix A. Theorem Proofs

**Proposition 1** (Simovici, 2007) When \( q = 2 \) the generalized variation of information, the Mirkin index, and the Rand index are linearly related: \( \text{VI}_2(U, V) = \frac{1}{N^2} \text{MK}(U, V) = \frac{N-1}{N^2}(1 - \text{RI}(U, V)) \).

**Proof**

\[
\text{VI}_q(U, V) = 2H_q(U, V) - H_q(U) - H_q(V)
\]

\[
= \frac{2}{q-1} \left(1 - \sum_{i=1}^{r} \sum_{j=1}^{c} \left( \frac{n_{ij}}{N} \right)^q \right) - \frac{1}{q-1} \left(1 - \sum_{i=1}^{r} \left( \frac{a_i}{N} \right)^q \right) - \frac{1}{q-1} \left(1 - \sum_{j=1}^{c} \left( \frac{b_j}{N} \right)^q \right)
\]

\[
= \frac{1}{(q-1)N^q} \left( \sum_{i=1}^{r} a_i^q + \sum_{j=1}^{c} b_j^q - 2 \sum_{i=1}^{r} \sum_{j=1}^{c} n_{ij}^q \right)
\]

When \( q = 2 \), \( \text{VI}_2(U, V) = \frac{1}{N^2} (\sum_i a_i^2 + \sum_j b_j^2 - 2 \sum_{i,j} n_{ij}^2) = \frac{1}{N^2} \text{MK}(U, V) = \frac{N-1}{N^2}(1 - \text{RI}(U, V)) \).

**Lemma 1** If \( S(U, V) \in \mathcal{L}_\phi \), when partitions \( U \) and \( V \) are random:

\[
E[S(U, V)] = \alpha + \beta \sum_{ij} E[\phi_{ij}(n_{ij})] \quad \text{where} \quad E[\phi_{ij}(n_{ij})] \quad \text{is}
\]

\[
\sum_{n_{ij}=\max\{0,a_i+b_j-N\}}^{\min\{a_i,b_j\}} \phi_{ij}(n_{ij}) \frac{a_i!b_j!(N-a_i)!(N-b_j)!}{N!n_{ij}!(a_i-n_{ij})!(b_j-n_{ij})!(N-a_i-b_j+n_{ij})!}
\]

**Proof** The expected value of \( S(U, V) \) according to the hypergeometric model of randomness is \( E[S(U, V)] = \sum_M S(M)P(M) \) where \( M \) is a contingency table generated via permutations. This is reduced to \( E[S(U, V)] = \sum_M (\alpha + \beta \sum_{ij} \phi_{ij}(n_{ij}))P(M) = \alpha + \beta \sum_M \sum_{ij} \phi_{ij}(n_{ij})P(M) \). Because of linearity of the expected value, it is possible to swap the summation over \( M \) and the one over cells obtaining \( \alpha + \beta \sum_{ij} \sum_{n_{ij}} \phi_{ij}(n_{ij})P(n_{ij}) = \alpha + \beta \sum_{ij} E[\phi_{ij}(n_{ij})] \) where \( n_{ij} \) is a hypergeometric distribution with the marginals \( a_i, b_j, \) and \( N \) as parameters, i.e. \( n_{ij} \sim \text{Hyp}(a_i, b_j, N) \).

**Theorem 1** When the partitions \( U \) and \( V \) are random:

i) \( E[H_q(U, V)] = \frac{1}{q-1} \left(1 - \frac{1}{N^q} \sum_{ij} E[n_{ij}^q] \right) \) with \( E[n_{ij}^q] \) from Eq. (10) with \( \phi_{ij}(n_{ij}) = n_{ij}^q \);

ii) \( E[\text{ML}_q(U, V)] = H_q(U) + H_q(V) - E[H_q(U, V)] \);

iii) \( E[\text{VI}_q(U, V)] = 2E[H_q(U, V)] - E[H_q(U)] - H_q(V) \).

**Proof** The results easily follow from Lemma 1 and the hypothesis of fixed marginals.
\textbf{Theorem 2} Using $E[n_{ij}^q]$ in Eq. (10) with $\phi_{ij}(n_{ij}) = n_{ij}^q$, the adjustments for chance for $\text{MI}_q(U, V)$ and $\text{VI}_q(U, V)$ are:

\[
\text{AMI}_q(U, V) = \text{AVI}_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\frac{1}{2} \left( \sum_i a_i^q + \sum_j b_j^q \right) - \sum_{ij} E[n_{ij}^q]}
\] (12)

\textbf{Proof} The using the upper bound $\frac{1}{2}(H_q(U) + H_q(V))$ to $\text{MI}_q$, $\text{AMI}_q$ and $\text{AVI}_q$ are equivalent. Therefore we compute $\text{AVI}_q$. The computational complexity of $\text{Proposition 2}$

\[
\text{AMI}_2(U, V) = \frac{E[\text{VI}_2] - \text{VI}_2}{E[\text{VI}_2] - \min \text{VI}_2} = \frac{\frac{N-1}{N}(\text{RI} - E[\text{RI}])}{\frac{N-1}{N}(\max \text{RI} - E[\text{RI}])} = \text{ARI}
\]

\textbf{Corollary 1} It holds true that:

\begin{enumerate}[(i)]
\item \( \lim_{q \to 1} \text{AMI}_q = \lim_{q \to 1} \text{AVI}_q = \text{AMI} = \text{AVI} \) with Shannon entropy;
\item \( \text{AMI}_2 = \text{AVI}_2 = \text{ARI} \).
\end{enumerate}

\textbf{Proof} Point (i) follows from the limit of the $q$-entropy when $q \to 1$. Point (ii) follows from:

\[
\text{AVI}_2 = \frac{E[\text{VI}_2] - \text{VI}_2}{E[\text{VI}_2] - \min \text{VI}_2} = \frac{\frac{N-1}{N}(\text{RI} - E[\text{RI}])}{\frac{N-1}{N}(\max \text{RI} - E[\text{RI}])} = \text{ARI}
\]

\textbf{Proposition 2} The computational complexity of $\text{AMI}_q$ is $O(N \cdot \max \{ r, c \})$.

\textbf{Proof} The computation of $P(n_{ij})$ where $n_{ij}$ is a hypergeometric distribution $\text{Hyp}(a_i, b_j, N)$ is linear in $N$. However, the computation of the expected value $E[n_{ij}^q] = \sum_{n_{ij}} n_{ij}^q P(n_{ij})$ can exploit the fact that $P(n_{ij})$ are computed iteratively: $P(n_{ij}+1) = P(n_{ij}) \frac{(a_i-n_{ij})(b_j-n_{ij})}{(n_{ij}+1)(N-a_i-b_j+n_{ij}+1)}$.

We compute $P(n_{ij})$ only for $\max \{ 0, a_i + b_j - N \}$. In both cases $P(n_{ij})$ can be computed in $O(\max \{ a_i, b_j \})$. We can compute all other probabilities iteratively as shown above in constant time. Therefore:

\[
\sum_{i=1}^{r} \sum_{j=1}^{c} \left( O(\max \{ a_i, b_j \}) + \sum_{n_{ij}=0}^{\min \{ a_i, b_j \}} O(1) \right) = \sum_{i=1}^{r} \sum_{j=1}^{c} O(\max \{ a_i, b_j \}) = \sum_{i=1}^{r} O(\max \{ ca_i, N \}) = O(\max \{ cN, rN \}) = O(N \cdot \max \{ c, r \})
\]

\textbf{Lemma 2} If $S(U, V) \in N_\phi$, then $\lim_{N \to \infty} E[S(U, V)] = \phi\left( \frac{a_1 b_1}{N}, \ldots, \frac{a_r b_r}{N} \right)$. 

21
Proof $S(U,V)$ can be written as $\phi(\frac{n_{ij}}{N}, \ldots, \frac{n_{ij}}{N}, \ldots, \frac{n_{ij}}{N})$. Let $X = (X_1, \ldots, X_{rc}) = (\frac{n_{ij}}{N}, \ldots, \frac{n_{ij}}{N}, \ldots, \frac{n_{ij}}{N})$ be a vector of $rc$ random variables where $n_{ij}$ is a hypergeometric distribution with the marginals as parameters: $a_i$, $b_j$ and $N$. The expected value of $\frac{n_{ij}}{N}$ is $E[\frac{n_{ij}}{N}] = \frac{1}{N} \frac{a_i b_j}{rc}$. Let $\mu = (\mu_1, \ldots, \mu_{rc}) = (E[X_1], \ldots, E[X_{rc}]) = (\frac{a_i}{N}, \ldots, \frac{a_i}{N}, \ldots, \frac{a_i}{N})$ be the vector of the expected values. The Taylor approximation of $S(U,V) = \phi(X)$ around $\mu$ is:

$$
\phi(X) \simeq \phi(\mu) + \sum_{t=1}^{rc} \frac{\partial \phi}{\partial X_t} (X_t - \mu_t) + \frac{1}{2} \sum_{t=1}^{rc} \sum_{s=1}^{rc} (X_t - \mu_t)(X_s - \mu_s) \frac{\partial^2 \phi}{\partial X_t \partial X_s} + \ldots
$$

Its expected value is (see Section 4.3 of (Ang and Tang, 2006)):

$$
E[\phi(X)] \simeq \phi(\mu) + \frac{1}{2} \sum_{t=1}^{rc} \sum_{s=1}^{rc} \text{Cov}(X_t, X_s) \frac{\partial^2 \phi}{\partial X_t \partial X_s} + \ldots
$$

We just analyse the second order remainder given that it dominates the higher order ones. Using the Cauchy-Schwarz inequality we have that $|\text{Cov}(X_t, X_s)| \leq \sqrt{\text{Var}(X_t)\text{Var}(X_s)}$. Each $X_t$ and $X_s$ is equal to $\frac{n_{ij}}{N}$ for some indexes $i$ and $j$. The variance of each $X_t$ and $X_s$ is therefore equal to $\text{Var}(\frac{n_{ij}}{N}) = \frac{1}{N^2} \frac{a_i b_j N - a_i N - b_j N}{N^2 N - 1}$. When the number of records is large also the marginals increase: $N \rightarrow +\infty \Rightarrow a_i \rightarrow +\infty$, and $b_j \rightarrow +\infty \forall i, j$. However, because of the permutation model, all the fractions $\frac{a_i}{N}$ and $\frac{b_j}{N}$ stay constant $\forall i, j$. Therefore, also $\mu$ is constant. However, at the limit of large $N$, the variance of $\frac{n_{ij}}{N}$ tends to 0: $\text{Var}(\frac{n_{ij}}{N}) = \frac{1}{N^2} \frac{a_i b_j}{N} \left(1 - \frac{a_i}{N}\right) \left(1 + \frac{1}{N - 1} - \frac{b_j}{N}\right) \rightarrow 0$. Therefore, at large $N$:

$$
E[\phi(X)] \simeq \phi(\mu) = \phi\left(\frac{a_1 b_1}{N N}, \ldots, \frac{a_i b_j}{N N}, \ldots, \frac{a_r b_c}{N N}\right)
$$

\[\square\]

Theorem 3 It holds true that:

i) $\lim_{N \rightarrow +\infty} E[H_q(U,V)] = H_q(U) + H_q(V) - (q - 1)H_q(U)H_q(V)$;

ii) $\lim_{N \rightarrow +\infty} E[Mq(U,V)] = (q - 1)H_q(U)H_q(V)$;

iii) $\lim_{N \rightarrow +\infty} E[Vq(U,V)] = H_q(U) + H_q(V) - 2(q - 1)H_q(U)H_q(V)$.

Proof $E[H_q(U,V)] = \frac{1}{q-1} \left(1 - \sum_{ij} E \left[ \left( \frac{n_{ij}}{N} \right)^q \right] \right)$ and according to Lemma 2 for large $N$:

$$
E[H_q(U,V)] \simeq \frac{1}{q-1} \left(1 - \sum_{ij} \left( \frac{a_i}{N} \right)^q \sum_j \left( \frac{b_j}{N} \right)^q \right).
$$

If we add an subtract
1 - \sum_i \left( \frac{a_i}{N} \right)^q - \sum_j \left( \frac{b_j}{N} \right)^q \) in the parenthesis above:

\[
E[H_q(U, V)] \simeq \frac{1}{q-1} \left( 1 - \sum_i \left( \frac{a_i}{N} \right)^q + \sum_j \left( \frac{b_j}{N} \right)^q \right) + 1 - \sum_i \left( \frac{a_i}{N} \right)^q - \sum_j \left( \frac{b_j}{N} \right)^q - 1 + \sum_i \left( \frac{a_i}{N} \right)^q + \sum_j \left( \frac{b_j}{N} \right)^q \\
= \frac{1}{q-1} \left( 1 - \sum_i \left( \frac{a_i}{N} \right)^q \right) + \frac{1}{q-1} \left( 1 - \sum_j \left( \frac{b_j}{N} \right)^q \right) + \frac{1}{q-1} \left( -1 - \sum_i \left( \frac{a_i}{N} \right)^q + \sum_j \left( \frac{b_j}{N} \right)^q \right) + \frac{1}{q-1} \left( \left( 1 - \sum_i \left( \frac{a_i}{N} \right)^q \right) \left( \sum_j \left( \frac{b_j}{N} \right)^q \right) \right) \\
= H_q(U) + H_q(V) + \frac{1}{q-1} \left( \left( 1 - \sum_i \left( \frac{a_i}{N} \right)^q \right) \left( \sum_j \left( \frac{b_j}{N} \right)^q \right) \right)
\]

Point ii) and iii) follow from Equations (6) and (7).

Lemma 3 If \( S(U, V) \in \mathcal{L}_\phi \), when partitions \( U \) and \( V \) are random:

\[
\text{Var}(S(U, V)) = \beta^2 \left( E \left[ \left( \sum_{ij} \phi_{ij}(n_{ij}) \right)^2 \right] - \left( \sum_{ij} E[\phi_{ij}(n_{ij})] \right)^2 \right),
\]

where

\[
E \left[ \left( \sum_{ij} \phi_{ij}(n_{ij}) \right)^2 \right]
\]

is equal to

\[
\sum_{ij} \sum_{\tilde{n}_{ij}} \phi(n_{ij})P(n_{ij}) \cdot \left[ \phi_{ij}(n_{ij}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j}} \phi_{i'j}(\tilde{n}_{i'j})P(\tilde{n}_{i'j}) + \sum_{j' \neq j} \sum_{\tilde{n}_{ij'}} \phi_{ij'}(\tilde{n}_{ij'}) + \sum_{i' \neq i} \sum_{\tilde{n}_{i'j'}} \phi_{i'j'}(\tilde{n}_{i'j'})P(\tilde{n}_{i'j'}) \right] \quad (13)
\]

with \( n_{ij} \sim \text{Hyp}(a_i, b_j, N) \), \( \tilde{n}_{i'j} \sim \text{Hyp}(b_j - n_{ij}, a_{i'}, N - a_i) \), \( \tilde{n}_{ij'} \sim \text{Hyp}(a_i - n_{ij}, b_{j'}, N - b_j) \), \( \tilde{n}_{i'j'} \sim \text{Hyp}(a_{i'}, b_{j'} - \tilde{n}_{ij'}, N - a_i) \) hypergeometric random variables.

Proof The proof follows Theorem 1 proof in Romano et al. (2014). Using the properties of the variance we can show that \( \text{Var}(S(U, V)) = \beta^2 \text{Var}(\sum_{ij} \phi_{ij}(n_{ij})) = \beta^2 \left( E[(\sum_{ij} \phi_{ij}(n_{ij}))^2] - \right) \)
\((\sum_{ij} E[\phi_{ij}(n_{ij})])^2\). \((E[\sum_{ij} \phi_{ij}(n_{ij})])^2 = (\sum_{ij} E[\phi_{ij}(n_{ij})])^2\) can be computed using Eq. (10). The first term in the sum is instead:

\[
E[\sum_{i,j} E[\phi_{ij}(n_{ij})|n_{i',j'}]] = \sum_{i,j} \sum_{i'',j''} \sum_{n_{i',j'}} \phi_{ij}(n_{ij}) \phi_{i'',j''}(n_{i',j'}) P(n_{ij}, n_{i',j'})
\]

We cannot find the exact form of the joint probability \(P(n_{ij}, n_{i',j'})\) thus we rewrite it as \(P(n_{ij})P(n_{i',j'}|n_{ij}) = P(n_{ij})P(\tilde{n}_{i',j'})\). The random variable \(n_{ij}\) is an hypergeometric distribution that simulates the experiment of sampling without replacement the \(a_i\) objects in the set \(u_i\) from a total of \(N\) objects. Sampling one of the \(b_j\) objects from \(v_j\) is defined as a success: \(n_{ij} \sim \text{Hyp}(a_i, b_j, N)\). The random variable \(\tilde{n}_{i',j'}\) has a different distribution depending on the possible combinations of indexes \(i, i', j, j'\). Thus \(E[\sum_{ij} \phi_{ij}(n_{ij})]\) is equal to:

\[
\sum_{ij} \sum_{i', j'} \sum_{n_{i',j'}} \phi_{ij}(n_{ij}) \phi_{i',j'}(n_{i',j'}) P(n_{ij}, n_{i',j'}) = \sum_{ij} \sum_{n_{ij}} \phi_{ij}(n_{ij}) \sum_{i', j'} \phi_{i',j'}(\tilde{n}_{i',j'}) P(\tilde{n}_{i',j'})
\]

which, by taking care of all possible combinations of \(i, i', j, j'\), is equal to:

\[
\sum_{ij} \phi_{ij}(n_{ij}) P(n_{ij}) \cdot \left[ \sum_{i'=i,j'=j} \phi_{i,j}(\tilde{n}_{i,j}) P(\tilde{n}_{i,j}) + \sum_{i' \neq i, j' \neq j} \phi_{i',j'}(\tilde{n}_{i',j'}) P(\tilde{n}_{i',j'}) \right] + \sum_{i' \neq i, j' \neq j} \phi_{i',j'}(\tilde{n}_{i',j'}) P(\tilde{n}_{i',j'})
\]

\[(17)\]

\[
(18)
\]

**Case 1:** \(i' = i \land j' = j\)

\(P(\tilde{n}_{ij}) = 1\) if and only if \(\tilde{n}_{ij} = n_{ij}\) and 0 otherwise. This case produces the first term \(\phi_{ij}(n_{ij})\) enclosed in square brackets.

**Case 2:** \(i' = i \land j' \neq j\)

In this case, the possible successes are the objects from the set \(v_{j'}\). We have already sampled \(n_{ij}\) objects and we are sampling from the whole set of objects excluding the set \(v_j\). Thus, \(\tilde{n}_{i,j'} \sim \text{Hyp}(a_i - n_{ij}, b_{j'}, N - b_j)\).

**Case 3:** \(i' \neq i \land j' = j\)

This case is symmetric to the previous one where \(a_{i'}\) is now the possible number of successes. Therefore \(\tilde{n}_{i',j} \sim \text{Hyp}(b_j - n_{ij}, a_{i'}, N - a_i)\).

**Case 4:** \(i' \neq i \land j' \neq j\)

In order compute \(P(\tilde{n}_{i',j'})\), we have to impose a further condition:

\[
P(\tilde{n}_{i',j'}) = \sum_{\tilde{n}_{i,j'}} P(\tilde{n}_{i,j'}|\tilde{n}_{i,j'}) P(\tilde{n}_{i,j'}) = \sum_{\tilde{n}_{i,j'}} P(\tilde{n}_{i,j'}) P(\tilde{n}_{i,j'})
\]
We are considering sampling the $a_i$ objects in $u_i$ from the whole set of objects excluding the $a_i$ objects from $u_i$. Just knowing that $n_{ij}$ objects have already been sampled from $u_i$ does not allow us to know how many objects from $v_j$ have also been sampled. If we know that $n_{ij'}$ is the number of objects sampled from $v_j'$, we know there are $b_j' - n_{ij'}$ possible successes and thus $\tilde{n}_{ij'}|n_{ij'} = \tilde{n}_{ij'} \sim \text{Hyp}(a_i', b_j' - \tilde{n}_{ij'}, N - a_i)$. So the last two terms in Eq. (18) can be put together:

$$
\sum_{i' \neq i, j' \neq j} \sum \phi_{i'j'}(\tilde{n}_{i'j'})P(\tilde{n}_{i'j'}) + \sum_{i' \neq i, j' \neq j} \sum \phi_{i'j'}(\tilde{n}_{i'j'})P(\tilde{n}_{i'j'})
$$

By putting everything together we get that $E[(\sum_{ij} \phi_{ij}(n_{ij}))^2]$ is equal to:

$$
\sum_{ij} \phi(n_{ij})P(n_{ij}) \cdot \left[ \sum_{i' \neq i} \phi_{i'j}(\tilde{n}_{i'j}) + \sum_{i' \neq i} \phi_{i'j}(\tilde{n}_{i'j}) \right] + \sum_{j' \neq j} \sum P(\tilde{n}_{ij'}) \left[ \sum_{i' \neq i} \phi_{i'j'}(\tilde{n}_{i'j'}) + \sum_{i' \neq i} \phi_{i'j'}(\tilde{n}_{i'j'}) \right]
$$

\[\square\]

**Theorem 5** Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, when the partitions $U$ and $V$ are random:

i) $\text{Var}(H_q(U, V)) = \frac{1}{(q-1)\cdot N^2} \left( E[(\sum_{ij} n_{ij}^q)^2] - (\sum_{ij} E[n_{ij}^q])^2 \right)$;

ii) $\text{Var}(\text{MI}_q(U, V)) = \text{Var}(H_q(U, V))$

iii) $\text{Var}(\text{VI}_q(U, V)) = 4\text{Var}(H_q(U, V))$

**Proof** The results follow from Lemma 3, the hypothesis of fixed marginals and properties of the variance. \[\square\]

**Theorem 6** Using Eqs. (10) and (13) with $\phi_{ij}(\cdot) = (\cdot)^q$, the standardized $\text{MI}_q(U, V)$ and the standardized $\text{VI}_q(U, V)$ are:

$$
\text{SMI}_q(U, V) = \text{SVI}_q(U, V) = \frac{\sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q]}{\sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (\sum_{ij} E[n_{ij}^q])^2}}
$$  (15)
Proof
For SMI₉: the numerator is equal to \( H_q(U, V) - E[H_q(U, V)] = \frac{1}{(q-1)N^q} \left( \sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q] \right) \).
According Theorem 5, the denominator is instead:
\[
\sqrt{\text{Var}(MI_q(U, V))} = \sqrt{\text{Var}(H_q(U, V))} = \frac{1}{(q-1)N^q} \sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (E[\sum_{ij} n_{ij}^q])^2}.
\]

For SVI₉: the numerator is equal to \( 2H_q(U, V) - 2E[H_q(U, V)] = \frac{2}{(q-1)N^q} \left( \sum_{ij} n_{ij}^q - \sum_{ij} E[n_{ij}^q] \right) \). According Theorem 5, the denominator is instead:
\[
\sqrt{\text{Var}(VI_q(U, V))} = \sqrt{4\text{Var}(H_q(U, V))} = \frac{2}{(q-1)N^q} \sqrt{E[(\sum_{ij} n_{ij}^q)^2] - (E[\sum_{ij} n_{ij}^q])^2}.
\]

Therefore, SMI₉ and SVI₉ are equivalent.

Corollary 2 It holds true that:
\( i) \lim_{q \to 1} SMI_q = \lim_{q \to 1} SVI_q = SMI = SVI = S_G \) with Shannon entropy;
\( ii) SMI_2 = SVI_2 = SRI \).

Proof Point \( i) \) follows from the limit of the \( q \)-entropy when \( q \to 1 \) and the linear relation of \( G \)-statistic to MI: \( G = 2NMI \). Point \( ii) \) follows from:
\[
\text{SVI}_2 = \frac{E[\text{VI}_2] - \text{VI}_2}{\sqrt{\text{Var}(\text{VI}_2)}} = \frac{N^{-1} \text{RI} - E[\text{RI}]}{\frac{N^{-1}}{N} \sqrt{\text{Var}(\text{RI})}} = SRI
\]

Proposition 3 The computational complexity of SMI₉ is \( O(N^3c \cdot \max\{c, r\}) \).

Proof Each summation in Eq. (13) can be bounded above by the maximum value of the cell marginals and each sum can be done in constant time. The last summation in Eq. (13) is:
\[
\sum_{c} \max\{a_i, b_{j'}\} \sum_{j'=1}^{r} \max\{a_{i'}, b_{j'}\} \sum_{i'=1}^{\max\{a_{i'}, b_{j'}\}} \sum_{\tilde{n}_{i'j'}=0}^{\max\{a_{i'}, b_{j'}\}} \sum_{\tilde{n}_{ij}=0}^{\max\{a_i, b_{j'}\}} O(1) = \sum_{c} \max\{a_i, b_{j'}\} \sum_{j'=1}^{r} \max\{a_{i'}, b_{j'}\} \sum_{i'=1}^{\max\{a_{i'}, b_{j'}\}} O(\max\{a_{i'}, b_{j'}\})
\]
\[
= \sum_{c} \max\{a_i, b_{j'}\} \sum_{j'=1}^{r} O(\max\{a_i, r b_{j'}, b_{j'} N, N r^2\})
\]
\[
= O(\max\{ca_i, a_i r N, N r^2\})
\]

The above term is thus the computational complexity of the inner loop. Using the same machinery one can prove that:

\[
\sum_{j=1}^{c} \sum_{i=1}^{r} \sum_{n_{ij}=0}^{\max\{a_{i},b_{j}\}} O(\max\{ca_{i}N,a_{i}rN,rN^{2}\}) = O(\max\{c^{2}N^{3},rcN^{3}\}) = O(N^{3}c \cdot \max\{c,r\})
\]

**Proposition 4** The p-value associated to the test for independence between \(U\) and \(V\) using \(\text{MI}_{q}(U,V)\) is smaller than:

\[
p\text{-value} = \frac{1}{1 + (\text{SMI}_{q}(U,V))^{2}}.
\]

**Proof** Let \(\text{MI}_{q}^{0}\) be the random variable under the null hypothesis of independence between partitions associated to the test statistic \(\text{MI}_{q}(U,V)\). The p-value is defined as:

\[
p\text{-value} = P\left(\text{MI}_{q}^{0} \geq \text{MI}_{q}(U,V)\right) = P\left(\frac{\text{MI}_{q}^{0} - E[\text{MI}_{q}(U,V)]}{\sqrt{\text{Var}([\text{MI}_{q}(U,V)])}} \geq \frac{\text{MI}_{q}(U,V) - E[\text{MI}_{q}(U,V)]}{\sqrt{\text{Var}([\text{MI}_{q}(U,V)])}}\right)
\]

Let \(Z\) be the standardized random variable \(\frac{\text{MI}_{q}^{0} - E[\text{MI}_{q}(U,V)]}{\sqrt{\text{Var}([\text{MI}_{q}(U,V)])}}\) then using the one side Chebyshev’s inequality also known as the Cantelli’s inequality (Ross, 2012):

\[
p\text{-value} = P(Z \geq \text{SMI}_{q}(U,V)) < \frac{1}{1 + \left(\text{SMI}_{q}(U,V)\right)^{2}}
\]

**Lemma 4** If \(S(U,V) \in \mathcal{N}_{\phi}\), then \(\lim_{N \to +\infty} \text{Var}(S(U,V)) = 0\).

**Proof** Let \(X = (X_{1}, \ldots, X_{rc}) = \left(\frac{n_{i1}}{N}, \ldots, \frac{n_{i1}}{N}, \ldots, \frac{n_{rj}}{N}, \ldots, \frac{n_{rj}}{N}\right)\) be a vector of \(rc\) random variables where \(n_{ij}\) is a hypergeometric distribution with the marginals as parameters: \(a_{i}, b_{j}\) and \(N\). Using the Taylor approximation (Ang and Tang, 2006) of \(S(U,V) = \phi(X)\), it is possible to show that:

\[
\text{Var}(\phi(X)) \simeq \sum_{t=1}^{rc} \sum_{s=1}^{rc} \text{Cov}(X_{t}, X_{s}) \frac{\partial \phi}{\partial X_{t}} \frac{\partial \phi}{\partial X_{s}} + \ldots
\]

Using the Cauchy-Schwartz inequality we have that \(|\text{Cov}(X_{t}, X_{s})| \leq \sqrt{\text{Var}(X_{t})\text{Var}(X_{s})}\). Each \(X_{t}\) and \(X_{s}\) is equal to \(\frac{n_{ij}}{N}\) for some indexes \(i\) and \(j\). The variance of each \(X_{t}\) and \(X_{s}\) is
therefore equal to $\text{Var}(\frac{n_{ij}N}{N}) = \frac{1}{N^2} \frac{a_i b_j N - a_i N - b_j N}{N^2}$. When the number of records is large also the marginals increase: $N \to +\infty \Rightarrow a_i \to +\infty$, and $b_j \to +\infty \forall i, j$. However because of the permutation model, all the fractions $\frac{a_i}{N}$ and $\frac{b_j}{N}$ stay constant $\forall i, j$. Therefore, at the limit of large $N$, the variance of $\frac{n_{ij}N}{N}$ tends to 0: $\text{Var}\left(\frac{n_{ij}N}{N}\right) = \frac{1}{N} \frac{a_i b_j}{N} \left(1 - \frac{a_i}{N}\right) \left(1 + \frac{1}{N-1} - \frac{b_j}{N}\right) \to 0$ and thus $\text{Var}(\phi(X))$ tends to 0.

**Theorem 7** It holds true that:

$$\lim_{N \to +\infty} \text{Var}(H_q(U,V)) = \lim_{N \to +\infty} \text{Var}(MI_q(U,V)) = \lim_{N \to +\infty} \text{Var}(VI_q(U,V)) = 0$$

(16)

**Proof** Trivially follows from Lemma 4. ■
