Abstract

We propose a two step algorithm based on $\ell_1/\ell_0$ regularization for the detection and estimation of parameters of a high dimensional change point regression model and provide the corresponding rates of convergence for the change point as well as the regression parameter estimates. Importantly, the computational cost of our estimator is only $2\cdot\text{Lasso}(n,p)$, where $\text{Lasso}(n,p)$ represents the computational burden of one Lasso optimization in a model of size $(n,p)$. In comparison, existing grid search based approaches to this problem require a computational cost of at least $n\cdot\text{Lasso}(n,p)$ optimizations. Additionally, the proposed method is shown to be able to consistently detect the case of ‘no change’, i.e., where no finite change point exists in the model. We allow the true change point parameter $\tau_0$ to possibly move to the boundaries of its parametric space, and the jump size $\|\beta_0 - \gamma_0\|_2$ to possibly diverge as $n$ increases. We then characterize the corresponding effects on the rates of convergence of the change point and regression estimates. In particular, we show that, while an increasing jump size may have a beneficial effect on the change point estimate, however the optimal rate of regression parameter estimates are preserved only up to a certain rate of the increasing jump size. This behavior in the rate of regression parameter estimates is unique to high dimensional change point regression models only. Simulations are performed to empirically evaluate performance of the proposed estimators. The methodology is applied to community level socio-economic data of the U.S., collected from the 1990 U.S. census and other sources.

Keywords: Change point regression, High dimensional models, $\ell_1, \ell_0$ regularization, Rate of convergence, Two phase regression
1. Introduction

Regression models are fundamental to supervised learning and statistical modelling of data collected from scientific phenomena. While applying regression models, one often assumes the regression parameters to be stable over time. However, this assumption may be rigid and may not hold in several environmental, biological and economic models, particularly when data is collected over an extended period of time. There are several approaches to model this dynamic phenomenon in regression parameters. One approach is to let the parameters change at certain unknown time points of the sampling period (Hinkley (1970), Hinkley (1972), Jandhyala and MacNeill (1997), Bai (1997), Jandhyala and Fotopoulos (1999), Fotopoulos et al. (2010) and Jandhyala et al. (2013)). Another closely related approach is to formulate the change point based on one or more covariate thresholds (Hinkley (1969), Koul and Qian (2002) and Koul et al. (2003)). In the literature, it is common to broadly call both as change point regression models. Such dynamic models have been found to have wide ranging applications in all areas of scientific inquiry (Reeves et al. (2007), Lund et al. (2007), and Liu et al. (2013)).

Technological advances in the past two decades have led to the wide availability of large scale/high dimensional data sets in several areas of applications such as genomics, social networking, empirical economics, finance etc. This has led to rapid development of high dimensional statistical methods. A large body of literature has now been developed pertaining to the study of regression models capable of allowing a vastly larger number of parameters $p$ than the sample size $n$. One of the most successful methods for analysing high dimensional regression models is the Lasso, which is based on the least squares loss and $\ell_1$ regularization (Tibshirani (1996)). Innumerable investigations have since been carried out to study the behavior of the Lasso estimator and its various modifications in many different settings (see e.g., Zou (2006), Zhao and Yu (2006), Bickel et al. (2009), Belloni et al. (2011), Belloni et al. (2017a), Kaul (2014), Kaul and Koul (2015), and the references therein). For a general overview on the developments of Lasso and its variants we refer to the monograph of Bühlmann and Van De Geer (2011) and the review article of Tibshirani (2011). All aforementioned articles provide results in a regression setting where the parameters are dynamically stable. In the recent past, work has also been carried out in the context of high dimensional change point models in an ‘only means’ setup, where change occurs in only the mean of time ordered independent random vectors, with the dimension of the observation vector being larger than the number of observations (Cho and Fryzlewicz (2015), Fryzlewicz (2014), and Wang and Samworth (2018) among others). Here the change is characterized in the sense of a dynamic mean vector. Another context in which high dimensional change point models have been investigated is that of a dynamic covariance structure which is related to the study of evolving networks (Gibberd and Roy (2017), and Atchade and Bybee (2017)). In contrast, change point methods for high dimensional linear regression models have received much less attention and only a select few articles have considered this problem in the recent literature (Ciuperca (2014), Zhang et al. (2015), Leonard and Bühlmann (2016), Lee et al. (2016), and Lee et al. (2018)).

In this paper, we consider a high dimensional linear regression model with a potential change point,

$$y_i = x_i^T \beta_0 1[w_i \leq \tau_0] + x_i^T \gamma_0 1[w_i > \tau_0] + \varepsilon_i, \quad i = 1, ..., n. \quad (1.1)$$
The observed variables in model (1.1) are, \( y_i \in \mathbb{R} \), the \( p \)-dimensional predictors \( x_i \in \mathbb{R}^p \), and change inducing variable \( w_i \in \mathbb{R} \), \( i = 1, \ldots, n \). The unknown parameters of interest are the regression parameters \( \beta_0, \gamma_0 \in \mathbb{R}^p \), and the change point \( \tau_0 \in \mathbb{R}^* := \mathbb{R} \cup \{-\infty\} \). The change point \( \tau_0 \) represents a threshold value of the variable \( w \) subsequent to which the regression parameter changes from its initial value \( \beta_0 \) to a new value \( \gamma_0 \). Note that, the ‘no change’ case is allowed by the model (1.1), since we allow \( \tau_0 = -\infty \), in its parametric space. In this case, model (1.1) reduces to an ordinary high dimensional linear regression model. The parametric space \( \mathbb{R}^* \) of \( \tau \) is restricted to only contain \(-\infty\), and not \( \infty \), since both of these points characterize the ‘no change’ scenario and are unidentifiable from each other. This differs from the usual characterization of the ‘no change’ case, which is typically defined by \( \beta_0 = \gamma_0 \) and \( \tau_0 \in \mathbb{R} \), for e.g. in Lee et al. (2016) and Lee et al. (2018). However it should be understood that this difference is only notational and both are characterizing the same null model. It should also be noted that the change point \( \tau_0 \in \mathbb{R}^* \), may itself depend on \( n \), i.e., as the sample size increases, the change point may shift its location. However, for clarity of exposition, this dependence is notionally suppressed in the rest of this article. Furthermore, we let \( p >> n \), so that model (1.1) corresponds to a high dimensional setting. Also, consistent with current literature, we assume that only a total of \( s \) components of \( \beta_0 \) and \( \gamma_0 \) are non-zero, i.e., \( \|\beta_0\|_0 + \|\gamma_0\|_0 \leq s \), where \( s < n \).

Recently, models similar to (1.1) have been studied by Ciuperca (2014), Zhang et al. (2015), Leonardi and Bühlmann (2016), Lee et al. (2016) and Lee et al. (2018). Similar to model (1.1), Lee et al. (2016) and Lee et al. (2018) consider a high dimensional model with only a single unknown change point, whereas, Zhang et al. (2015), and Leonardi and Bühlmann (2016) consider a model where multiple change points may be present in the model. The articles Zhang et al. (2015) and Ciuperca (2014) consider a multiple change point setting where the dimension \( p \) of the regression parameters is fixed. The common thread in these articles is to provide regularized estimators for the parameters \( \beta, \gamma, \tau \) and study their rates of convergence under different norms. In an earlier work, Wu (2008) provided an information-based criterion for carrying out change point analysis and variable selection in the fixed \( p \) setting; this methodology, however is not extendable to the high dimensional case. While these articles make important contributions to this fast emerging area, many aspects of this problem remain to be understood. For example, existing methods may be unable to satisfactorily detect the ‘no change’ case, these estimation methods may be computationally challenging to implement, and the underlying technical assumptions required for their theoretical validity may be restrictive.

The most commonly applied approach to estimating parameters of models such as (1.1) with a single change point is to consider,

\[
(\hat{\beta}, \hat{\gamma}, \hat{\tau}) = \arg\min_{\beta, \gamma \in \mathbb{R}^p, \tau \in \mathcal{T}} \left\{ \frac{1}{n} \sum_{i=1}^{n} \text{loss}(\text{data}, \beta, \gamma, \tau) + \text{pen}(\beta, \gamma, \tau) \right\},
\]

(1.2)

where \( \text{loss}(\text{data}, \beta, \gamma, \tau) \) is an appropriately chosen loss function, and \( \text{pen}(\beta, \gamma, \tau) \) is a suitably defined penalty function on the parameters \( \beta, \gamma, \tau \) (e.g., Lee et al. (2016), Lee et al. (2018) and (5.1) ). Here \( \mathcal{T} \) is a restriction on the parametric space of the change point parameter \( \tau \). The loss function in (1.2) is nonconvex and consequently a direct optimization of (1.2) is typically computationally infeasible. To circumvent this difficulty, the space \( \mathcal{T} \)
is usually broken into a grid of points $T^*$, and $\hat{\beta}(\tau), \hat{\gamma}(\tau)$ are computed for each $\tau \in T^*$. The estimate $\hat{\tau}$ of the change point $\tau_0$ is then obtained as that $\tau \in T^*$ which minimizes the objective function in (1.2) over $\hat{\beta}(\tau), \hat{\gamma}(\tau)$. When the loss function is least squares and the penalty is of an $\ell_1$-type, the computational cost of the above grid search is $|T^*|\text{Lasso}(n,p)$, where $|T^*|$ is typically of order $n$. Note that this grid search mechanism becomes computationally intensive as $n,p$ increase. In the case of multiple change points, Zhang et al. (2015), and Leonardi and Bühlmann (2016) provide dynamic programming approaches that can estimate the number and locations of change points with the same $n\text{Lasso}(n,p)$ computational cost.

In this article we develop a two step algorithm for detection and estimation of parameters of model (1.1), so that a full grid search is avoided even as the near optimal rates of all parameter estimates are preserved. The idea for developing such an algorithm originates from the following simple and yet surprising numerical observation. Suppose we first choose virtually any initial value $\tau^{(0)} \in \text{Supp}(w)$, separated from its boundaries and then compute regression coefficients $\hat{\beta}^{(0)}, \hat{\gamma}^{(0)}$ on the binary partition $\{i; i \in \{1,..,n\}, w_i \leq \tau^{(0)}\}$ and $\{i; i \in \{1,..,n\}, w_i > \tau^{(0)}\}$ respectively. Then a single update of the change point estimate obtained by optimization of the least squares loss over the change point parameter, using the previously obtained regression parameter estimates $\hat{\beta}^{(0)}, \hat{\gamma}^{(0)}$, yields a very precise estimate of the unknown change point, where the precision of this estimate is indistinguishable from existing full grid search approaches in any uniform sense. This simple numerical observation is very surprising, since it suggests that any initial $\tau^{(0)}$ which carries even a ‘fractional amount of information’ on the unknown $\tau_0$ (this notion is described precisely later in Section 2), can be utilized to obtain an updated estimate $\hat{\tau}^{(1)}$ in a single step, which lies in a near optimal neighborhood of $\tau_0$. In other words, the single step update process pulls in the initial guess $\tau^{(0)}$ from a much wider (nearly arbitrary) neighborhood of $\tau_0$, to a near optimal neighborhood of $\tau_0$. The usefulness of this process is immediate, as it removes the necessity of a grid search. The main contribution of this article is to develop a mathematical treatment of this two step algorithm. In doing so we also allow the possibility of ‘no change’ in the model (1.1).

More precisely, in this article we propose estimators based on $\ell_1/\ell_0$ regularization for the parameters $\tau_0$, $\beta_0$, and $\gamma_0$ of model (1.1). The proposed methodology completely avoids a grid search approach for locating the unknown change point, consequently has a computational cost of only $2\text{Lasso}(n,p)$, significantly below the $n\text{Lasso}(n,p)$ cost of existing methods. A second important novelty of the proposed method, is its ability to detect the ‘no change’ case, which is achieved by a $\ell_0$ regularization in the change point estimator. From a technical perspective, the rates of convergence associated with the proposed estimators are such that they are optimal for the regression parameter estimates and match the best rate of convergence available in the literature for estimating the change point. Before we describe our proposed methodology in Section 2, we outline below the notations used in this paper.

**Notation:** Throughout the paper, for any vector $\delta \in \mathbb{R}^p$, $\|\delta\|_0$ represents the number of non-zero components in $\delta$. The norms $\|\delta\|_1$ and $\|\delta\|_2$ represent the standard 1-norm and Euclidean norm, respectively. The norm $\|\delta\|_\infty$ represents the sup norm, i.e., the maximum of absolute values of all elements. For any set of indices $T \subseteq \{1,\ldots,p\}$, let $\delta_T = (\delta_j)_{j \in T}$ represent a sub-vector of $\delta$ containing components corresponding to the indices in $T$. Also,
we let $|T|$ represent the cardinality of the set $T$. The notation $1[\cdot]$ represents the usual indicator function. We denote by $a \land b = \min\{a, b\}$, and $a \lor b = \max\{a, b\}$, for any $a, b \in \mathbb{R}$. In the following, let Supp($w$) represent the support of the distribution of $w$ and $\Phi(\cdot)$ be its cdf. Also denote by $\Phi_{\min}(\tau_0) = \Phi(\tau_0) \land (1 - \Phi(\tau_0))$. We shall use the following notation to represent generic constants that may be different from one term to the next. For example, $0 < c_u < \infty$ represent universal constants, whereas $0 < c_m < \infty$ are constants that depend on model parameters such as variance parameters of underlying distributions. The generic constants $0 < c_1, c_2 < \infty$ are used to denote constants that may depend on both $c_u$, and $c_m$. Lastly, we shall denote by $\mathbb{R}^* := \mathbb{R} \cup \{-\infty\}$, as the extended Euclidean space with negative infinity included. In the following, without loss of generality we assume that Supp($w$) = $\mathbb{R}$.

2. Methodology and Related Work

We begin this section by describing the proposed methodology for the detection and estimation of parameters of model (1.1). For this purpose we require the following notation. Let for any $\tau \in \mathbb{R}^*$, $\beta, \gamma \in \mathbb{R}^p$,

$$Q(\tau, \beta, \gamma) = \frac{1}{n} \sum_{i=1}^{n} (y_i - x_i^T \beta)^2 1[w_i \leq \tau] + \frac{1}{n} \sum_{i=1}^{n} (y_i - x_i^T \gamma)^2 1[w_i > \tau].$$

(2.1)

Additionally define the following Condition I that shall serve as an initializing condition required for the construction of our proposed algorithm.

**Condition I:** Let $u_n^{(0)}$ be a non-negative sequence defined as,

$$u_n^{(0)} = 1 \land c_u \left( \frac{s \log p}{n l_n^2} \right)^{\frac{1}{k}}, \quad \text{for any constants, } k \in [1, \infty), \quad \text{and } c_u > 0.$$ \hspace{1cm} (2.2)

where $0 < l_n \leq 1/2$ is any non-negative sequence. Then, assume that the initializer $\tau^{(0)}$ satisfies,

$$\Phi_{\min}(\tau^{(0)}) \geq c_u l_n, \quad \text{and } |\Phi(\tau^{(0)}) - \Phi(\tau_0)| \leq u_n^{(0)}.$$ \hspace{1cm} (2.3)

In the above Condition I, the sequence $l_n$ and the constant $k$ are arbitrary, subject to satisfying Condition A(iii) to follow. The rate of the sequence $l_n$ shall control the ability of Algorithm 1 to detect a finite change point near the boundaries of $\mathbb{R}$. Specifically Algorithm 1 shall be able to detect a finite change point (when it exists), such that $\Phi_{\min}(\tau_0)$ is of order at least that of $l_n$. In the case where it is assumed that, either $\Phi(\tau_0) = 0$ or $\Phi_{\min}(\tau_0) \geq c_u > 0$, then we can set $l_n \geq c_u$. Here, Algorithm 1 will be able to distinguish between the two cases, whether (a) there is no change point, $\Phi(\tau_0) = 0$ or (b) there is a finite change point $\tau_0 \in \mathbb{R}$ such that $\Phi(\tau_0)$ is bounded below.\(^c\)

Then, the two step algorithm which we propose to obtain change point and regression coefficient estimates is described in Algorithm 1 below.

---

\(^a\) Here, define $1[w_i \leq \tau] = 0$, for $\tau = -\infty$.

\(^b\) Note here that the constant $k$ is arbitrary, hence it can itself depend on initial $\tau^{(0)}$, i.e., the farther the guess $\tau^{(0)}$ is from $\tau_0$ the larger $k$ can be chosen in order to satisfy Condition I.

\(^c\) The quantities $l_n$ and $k$ are only required for analysis of Algorithm 1. These quantities play no role in its implementation.
Algorithm 1: Detection and estimation of change point and regression parameters

**Step 0 (Initialize):** Choose any initial value $\tau^{(0)} \in \mathbb{R}$ satisfying Condition I. Compute the initial regression parameter estimates,

$$
(\hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) = \arg \min_{\beta, \gamma \in \mathbb{R}^p} \left\{ Q(\tau^{(0)}, \beta, \gamma) + \lambda_1 \| (\beta^T, \gamma^T)^T \|_1 \right\}, \quad \lambda_1 > 0.
$$

**Step 1:** Update $\tau^{(0)}$ to obtain the change point estimate $\hat{\tau}^{(1)}$ where

$$
\hat{\tau}^{(1)} = \arg \min_{\tau \in \mathbb{R}} \left\{ Q(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) + \mu \| \Phi(\tau) \|_0 \right\}, \quad \mu > 0.
$$

**Step 2:** Update $(\hat{\beta}^{(0)}, \hat{\gamma}^{(0)})$ to obtain regression parameter estimates $(\hat{\beta}^{(1)}, \hat{\gamma}^{(1)})$ where,

$$
(\hat{\beta}^{(1)}, \hat{\gamma}^{(1)}) = \arg \min_{\beta, \gamma \in \mathbb{R}^p} \left\{ Q(\hat{\tau}^{(1)}, \beta, \gamma) + \lambda_2 \| (\beta^T, \gamma^T)^T \|_1 \right\}, \quad \lambda_2 > 0.
$$

A first concern that may arise to reader regarding Step 0 of Algorithm 1 pertains to the initializing conditions in (2.3) of Condition I. The first of these conditions is clearly innocuous, all it requires is the initial user chosen $\tau^{(0)}$ to be marginally away from the boundaries of $\mathbb{R}$. The second condition in (2.3) requires that the initial value $\tau^{(0)}$ be in an $u^{(0)}_n$-neighborhood of $\tau_0$. While at first, this might come across as a limitation of the algorithm, however the following discussion shall show how broad this $u^{(0)}_n$-neighborhood truly can be. First note that the constant $k \in [1, \infty)$ is arbitrarily large, subject to Condition A(iii), i.e., this condition is adaptable to the user chosen value of the initializer $\tau^{(0)}$. In other words, the farther the user chosen $\tau^{(0)}$ is from the true change point $\tau_0$, the larger the value of $k$ can be, in order to satisfy this condition. Additionally, note that the largest possible distance (in the cdf scale) between any two $\tau_1, \tau_2 \in \mathbb{R}$, is such that $|\Phi(\tau_1) - \Phi(\tau_2)| \leq 1$. Now for $c_u = 1$, consider first the disallowed case of $k = \infty$, then the initial condition is trivially satisfied, since $|\Phi(\tau^{(0)}) - \Phi(\tau_0)| \leq 1$. Thus, virtually any initial value in the parametric space of $\tau_0$, separated from its boundaries, will satisfy the required initial condition for a large enough $k \in [1, \infty)$, thereby illustrating that this initial condition is in fact very mild. Remarkably, one of our main results shows that, under suitable conditions, the updated change point estimate $\hat{\tau}^{(1)}$ of Step 1 of Algorithm 1, will satisfy optimal error bounds, irrespective of the value of $k$. Simply stated, the update in Step 1 sharpens the initial change point guess from any arbitrary fractional rate to a near optimal rate. The condition (2.3), also provides a precise description of the notion of ‘fractional information’ mentioned in the introduction section. The sequence $u^{(0)}_n$ forms a metric measuring the amount of information in the guess $\tau^{(0)}$ about $\tau_0$, and the existence of a finite $k < \infty$ provides a way of saying that the guess $\tau^{(0)}$ possesses some fractional amount of information on $\tau_0$.

To numerically illustrate this surprising phenomenon, in Section 5 we use the ‘no information’ initializer $\tau^{(0)} = w^{(0.5)}$, i.e. the 50th percentile of $w$.\(^d\) Note that this choice is

\(^d\) Note that while the initializing $\tau^{(0)}$ in Step 0 is chosen in $\mathbb{R}$, however the optimization in Step 1 is performed over the extended Euclidean space $\mathbb{R}^* = \mathbb{R} \cup \{-\infty\}$.\(^e\) The 50th percentile is the best ‘no information’ guess, since it is the empirical guess that is equidistant to the ends of the support of $w$.\(^
the most sensible value of the initializer in the absence of any information about $\tau_0$. These numerical results provide strong evidence to support Algorithm 1 by showing that the precision of the estimates obtained from the proposed method are in fact indistinguishable from existing grid search type approaches, and are obtained with a small fraction of the computational burden. Another equivalent way of viewing the above discussion is that, if we pick two distinct initializers $\tau_1^{(0)}$ and $\tau_2^{(0)}$ carrying some fractional information about $\tau_0$, i.e., they satisfy the initializing condition for some $1 \leq k_1 < k_2 < \infty$, respectively ($\tau_1^{(0)}$ is closer to $\tau_0$ than $\tau_2^{(0)}$), then, the corresponding updated change point estimates $\hat{\tau}_1^{(1)}$, $\hat{\tau}_2^{(1)}$ will both be in a near optimal neighborhood of $\tau_0$. This basically implies that the quality of the guess does not influence the updated estimate in its eventual rate of convergence. This observation is also numerically illustrated in Section 5.

Finally, we also mention that a slight relaxation of Condition I is also possible, specifically, the sequence $u_n^{(0)}$ in this condition can instead be relaxed to $u_n^{(0)} = 1 \land c_u (\frac{1}{k})^1/k$, for any constants $k \in [1, \infty)$ and any $c_u > 0$, while preserving all results to follow. However, Condition I in its current form provides a coherence with other noise bounds that show up in the statement and proof of our results, and thus is a notationally convenient representation. Furthermore, this relaxation of Condition I shall not yield error bounds that are any sharper than those to follow.

A second concern that may arise to the reader regarding implementation of Algorithm 1 is the feasibility of implementing Step 1. At first, this optimization seems intractable owing to its nonsmooth, nonconvex (with no apparent convex relaxations) construction. However, upon closer inspection, it is observed that the loss function $Q(\cdot, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)})$ in Step 1 is a step function with step changes occurring at any point on the one-dimensional grid $(-\infty, w_1, w_2, ..., w_n)^T$. Secondly, the $\ell_0$ term in the objective function only depends on whether $\Phi(\tau)$ is zero or non zero. This implies that the distance between any two $\tau_1$ and $\tau_2$ does not influence the value of the $\ell_0$ norm (note that this will not be the case if instead an $\ell_1$ norm is used). These two observations together imply that any global optimum achieved in the extended Euclidean space $\mathbb{R}_\star$ will also be attained at some point on the finite grid $(-\infty, w_1, w_2, ..., w_n)^T$. An illustration of this step behavior is provided in Figure 1.

A final concern in implementing Step 1 is that it requires knowledge of the distribution function $\Phi(\cdot)$, which is typically unknown. This concern is also easily overcome upon observing that the objective function in Step 1 is a step function over the grid $(-\infty, w_1, w_2, ..., w_n)^T$. Specifically, on this grid, the term $\|\Phi(\tau)\|_0 = \|\tau\|_0$, where $\|\tau\|_0 = 1$, if $\tau \in \{w_1, ..., w_n\}$ and $\|\tau\|_0 = 0$, if $\tau = -\infty$.

In view of the above discussion, Step 1 of Algorithm 1 can be replaced by the following optimization,

$$\hat{\tau}^{(1)} = \arg\min_{\tau \in (-\infty) \cup \{w_1, ..., w_n\}} \left\{ Q(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) + \mu \|\tau\|_0^\gamma \right\}, \quad \mu > 0.$$  \hspace{1cm} (2.5)

Thus, the optimization (2.4) in Step 1 of Algorithm 1 is reduced to the optimization (2.5), which can be easily solved in negligible time by explicitly computing $n$ values of the objective function and then locating the minimum.
Figure 1: Step behavior of the function $Q(\cdot, \hat{\beta}, \hat{\gamma}) + \mu \|\Phi(\tau)\|_0$, with $\mu = 0.1$, evaluated over grid of points $\{-\infty\} \cup \{0, 0.01, ..., 1\}$. Here $w_i \sim U(0, 1)$, $n = 6$, $\tau_0 = 0.25$, $p = 3$, $\beta_0 = (1, 0, 0)^T$, $\gamma_0 = (0, 1, 0)^T$, and we use $\hat{\beta} = (0.41, 0, 0)^T$, $\hat{\gamma} = (0.13, 0.92, 0)^T$. The realizations $\{w_1, ..., w_n\}$ have been sorted (ascending) in the illustration. Observe that step changes occur at $-\{\infty\} \cup \{w_1, w_2, ..., w_n\}$.

Another note of interest is the convenience of separability in computing the optimizers $\hat{\beta}, \hat{\gamma}$ in Step 0 and Step 2, i.e., for any fixed $\tau$, we can obtain

$$\hat{\beta}(\tau) = \arg\min_{\beta \in \mathbb{R}^p} \left\{ \frac{1}{n} \sum_{i: w_i \leq \tau} (y_i - x_i^T \beta)^2 + \lambda_1 \|\beta\|_1 \right\}, \quad (2.6)$$

$$\hat{\gamma}(\tau) = \arg\min_{\gamma \in \mathbb{R}^p} \left\{ \frac{1}{n} \sum_{i: w_i > \tau} (y_i - x_i^T \gamma)^2 + \lambda_1 \|\gamma\|_1 \right\}. \quad (2.7)$$

These are ordinary Lasso optimizations and can be carried out by any one of the several methods available in the literature. Some of these methods include, coordinate or gradient descent algorithms (see, e.g. Hastie et al. (2015)), or via interior point methods for linear optimization under second order conic constraints (see, e.g., Koenker and Mizera (2014)).

The main results of this article establish selection consistency of the unknown change point and provide finite sample bounds for the error in estimates obtained from Algorithm 1 under suitable conditions. Let $\xi_n := \|\beta_0 - \gamma_0\|_2$ be the jump size between the pre and post regression parameters. Then the specific results we derive are,

(i) If $\Phi(\tau_0) = 0$, then $\Phi(\hat{\tau}^{(1)}) = 0$, \hspace{1cm} (2.8)

(ii) If $\Phi_{\min}(\tau_0) \geq c_n t_n$, then $|\Phi(\hat{\tau}^{(1)}) - \Phi(\tau_0)| \leq t_n := c_n c_m \max \left\{ \frac{s \log p}{n}, \frac{1}{(1 \lor \xi_n^2)n^2}, \frac{s \log p}{n} \right\}$,

(iii) $\|\hat{\beta}^{(1)} - \beta_0\|_q \leq c_n c_m s^{1/q} \frac{1}{\Phi_{\min}(\tau_0)} \max \left\{ \sqrt{\frac{\log p}{n}, \xi_n t_n} \right\}$, \hspace{0.5cm} q = 1, 2,

(iv) $\|\hat{\gamma}^{(1)} - \gamma_0\|_q \leq c_n c_m s^{1/q} \frac{1}{\Phi_{\min}(\tau_0)} \max \left\{ \sqrt{\frac{\log p}{n}, \xi_n t_n} \right\}$, \hspace{0.5cm} q = 1, 2,

with probability at least $1 - c_1 \exp(-c_2 \log p)$, for $n$ sufficiently large.

These and other related results about estimates from Algorithm 1 are covered in Sections 3 and 4. The sharpness and/or near optimality of the above bounds may be observed from
the following special case. Upon letting \( \xi_n s \sqrt{\log p/n} \to 0 \), and \( l_n \geq c_u \), in (2.8), the last three results of (2.8) reduce to,

\[
(i) \quad \text{If } \Phi_{\text{min}}(\tau_0) \geq c_u l_n, \text{ then } |\Phi(\hat{s}^{(1)}) - \Phi(\tau_0)| \leq c_u c_m s \log p \frac{\sqrt{n}}{n},
\]

\[
(ii) \quad \|\hat{\beta}^{(1)} - \beta_0\|_q \leq c_u c_m s \sqrt{\frac{\log p}{n}}, \quad q = 1, 2,
\]

\[
(iii) \quad \|\hat{\gamma}^{(1)} - \gamma_0\|_q \leq c_u c_m s \sqrt{\frac{\log p}{n}}, \quad q = 1, 2,
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \), for \( n \) sufficiently large.

In an ordinary high dimensional linear regression model without change points, it has been shown that the optimal rate of convergence for regression estimates is \( \sqrt{s \log p/n} \) under the \( \ell_2 \) norm (see, e.g., Ye and Zhang (2010), Raskutti et al. (2011), and Belloni et al. (2017b)). This implies that the rate of convergence of the regression estimates from Algorithm 1 (which stops after one iteration) cannot be uniformly improved upon by carrying out further iterations (over subgaussian distributions). Also, the rate of convergence of the change point estimate in (2.9) is the fastest available rate in the literature. We shall now state the conditions under which the results of this article are derived.

**Condition A (assumptions on model parameters):**

(i) Let \( S = S_1 \cup S_2 \), where \( S_1 = \{ j; \beta_{0j} \neq 0 \} \) and \( S_2 = \{ j; \gamma_{0j} \neq 0 \} \). Then for some \( s = s_n \geq 1 \), we assume that \( |S| \leq s \).

(ii) The model dimensions \( s, p, n \), satisfy \( s \log p/n \to 0 \). Additionally, the sequence \( l_n \) of Condition 1 satisfies \( s \log p/nl_n^2 \to 0 \).

(iii) If a finite change point exists, i.e., \( \Phi_{\text{min}}(\tau_0) > 0 \), then the sequence \( l_n \) and constant \( k \in [1, \infty) \) of Condition 1 satisfy

\[
\frac{s}{l_n^2} \left( \frac{s \log p}{nl_n^2} \right)^{\frac{k}{2}} \to 0.
\]

Additionally, in this case \( \Phi_{\text{min}}(\tau_0) \geq c_u l_n \).

(iv) If \( \Phi_{\text{min}}(\tau_0) > 0 \), then the jump size is bounded below by a constant, i.e, \( \xi_n := \|\beta_0 - \gamma_0\|_2 > c > 0 \).

**Condition B (assumptions on model distributions):**

(i) The vectors \( x_i = (x_{i1}, \ldots, x_{ip})^T, i = 1, \ldots, n \), are i.i.d subgaussian\(^f\) with mean vector zero, and variance parameter \( \sigma_x^2 \leq C \). Furthermore, the covariance matrix \( \Sigma := Ex_i x_i^T \) has bounded eigenvalues, i.e., \( 0 < \kappa \leq \min_{\text{eigen}(\Sigma)} < \max_{\text{eigen}(\Sigma)} \leq \phi < \infty \).

(ii) The errors \( \varepsilon_i \)'s are i.i.d. subgaussian with mean zero and variance parameter \( \sigma^2_\varepsilon \leq C \).

(iii) The variables \( w_i, i = 1, \ldots, n \) are i.i.d. r.v.'s (continuous or discrete), with its cdf \( \Phi(a) = P(w_i \leq a), \ a \in \mathbb{R} \).

---

\(^f\) Recall that for \( \alpha > 0 \), the random variable \( \eta \) is said to be \( \alpha \)-subgaussian if, for all \( t \in \mathbb{R} \), \( E[\exp(t\eta)] \leq \exp(\alpha^2 t^2/2) \). Similarly, a random vector \( \xi \in \mathbb{R}^p \) is said to be \( \alpha \)-subgaussian if the inner products \( \langle \xi, v \rangle \) are \( \alpha \)-subgaussian for any \( v \in \mathbb{R}^p \) with \( \|v\|_2 = 1 \).
(iv) The r.v.'s $x_i, w_i, \varepsilon_i$ are independent of each other.

Conditions A(i) and A(ii) together form the usual sparsity assumption of high dimensional models. Conditions A(ii) and A(iii) are both restrictions on the model dimensions and in fact A(ii) is implied by A(iii) when it is applicable. However, both conditions are stated here since some of our results in Sections 3 and 4, hold under the weaker Condition A(ii). The Condition A(iii) is on the model parameters and also related to the initial condition of Condition I, via the sequence $l_n$ and the constant $k \in [1, \infty)$. This condition assumes the only additional control on how large a constant $k$ and how small the sequence $l_n$, can be tolerated by Algorithm 1, given the model dimensions. Heuristically, this condition ensures that the fractional information possessed by the initial guess $\tau(0)$, is not dominated by the noise induced in the linear system due to its large dimensions. Note that Condition A(iii) is only assumed if a change point exists, i.e., $\Phi_{\min}(\tau_0) > 0$. In the case of ‘no change’ in model (1.1), i.e., $\Phi(\tau_0) = 0$, any initial value $\tau^{(0)}$ satisfying $\Phi(\tau^{(0)}) \geq c_u l_n$, i.e., separated from the boundaries of $\mathbb{R}$, can be used to initialize Algorithm 1. A secondary purpose that Condition A(iii) serves is to ensure that if a finite change point exists, then, to keep $\Phi_{\min}(\tau_0) \geq c_u l_n$ away from the boundaries of $(0,1)$, whenever a finite change point exists in the model. Note that, this condition does not assume lower boundedness of $\Phi_{\min}(\tau_0)$ as is commonly the case in the literature, since the sequence $l_n$ may converge to zero. Finally, Condition A(iv) requires that if a finite change point exists, then the corresponding jump size $\xi_n$ is bounded below. We also mention here that we do not make any assumptions on the upper bound of $\xi_n$, and this jump size is allowed to possibly diverge with $n$.

The subgaussian assumptions in Conditions B(i) and B(ii) are now standard in high dimensional linear regression models and are known to accommodate a large class of random designs. In ordinary high dimensional linear regression, these assumptions are used to establish well behaved restricted eigenvalues of the Gram matrix $\sum x_i x_i^T / n$ (Raskutti et al. (2010), and Rudelson and Zhou (2012)), which are in turn used to derive convergence rates of $\ell_1$ regularized estimators (Bickel et al. (2009), and several others). These conditions play a similar role in our change point setup.

One main advantage of the proposed Algorithm 1 over existing methods is its ability to provide near optimal estimates without a grid search. As mentioned earlier in the article, the computational cost of Algorithm 1 is $2\text{Lasso}(n,p)$, significantly below the $n\text{Lasso}(n,p)$ cost of existing methods and is thus scalable to deal with large data. A novelty of Algorithm 1 in comparison to those proposed in Leonardi and Bühlmann (2016), Lee et al. (2016) and Lee et al. (2018) is its ability to detect the case where $\Phi(\tau_0) = 0$. This is relevant since it removes the necessity to pre-test for the existence of a change point. In contrast, while the methods of Lee et al. (2016), and Lee et al. (2018) are implementable in the case of no change point, they are however unable to detect the absence of the change point. Instead, in this case of $\Phi(\tau_0) = 0$, these methods return a valid $2p$ dimensional estimate $(\hat{\gamma}^T, \hat{\alpha}^T)^T$, where $\alpha_0 = \beta_0 - \gamma_0$, that can be used for predictive purposes using the model (1.1). Note that, the ability to detect the absence of a change point is a stronger statement and may provide additional relevant information, while also preserving the interpretable $p$ dimensional linear regression model in the case where $\Phi(\tau_0) = 0$.

The organization of the remainder of this article is as follows. Section 3 develops preliminary results required for analysis of estimates given by Algorithm 1 and Section 4 provides the main results regarding estimates obtained from Algorithm 1. Proofs of all results are
High dimensional change point regression is given in Appendix A, while Appendix B consists of some relevant auxiliary results from the literature, stated without proofs. The performance of Algorithm 1 is empirically evaluated in Section 5. In this numerical section, the implementation of Algorithm 1 assumes no prior information of the unknown change point $\tau_0$, additionally we numerically illustrate that the quality of the initial guess has no discernible impact on the final estimates and finally, we also show that the precision of the proposed estimates is indistinguishable from grid search approaches. Section 6 consists of an application of the proposed methodology to socio-economic data of U.S. collected from the 1990 U.S. census, and other sources.

3. Preliminary Results

In this section we present preliminary results that are important for stating and proving our main results in Section 4. First, for any fixed $\tau$, we define

$$\zeta_i(\tau) = \begin{cases} 1 & \text{if } \tau > \tau_0 \\ 1 & \text{if } \tau \leq \tau_0 \text{ and } \tau_0 < w_i \leq \tau \\ 1 & \text{if } \tau \leq \tau_0 \end{cases}$$

Then clearly, for any fixed $\tau \in \mathbb{R}$, $E\zeta_i(\tau) := \Phi^*(\tau_0, \tau) = |\Phi(\tau) - \Phi(\tau_0)|$. We shall now state a key result that uniformly controls (over $\tau$) the quantity $n^{-1} \sum_{i=1}^n \zeta_i(\tau)$.

**Lemma 3.1** Let $u_n$, and $v_n$ be any non-negative sequences such that $v_n \geq c \log p/n$, $c > 0$ and let $T(\tau_0, u_n) = \{\tau : \Phi^*(\tau_0, \tau) \leq u_n\}$ be a $u_n$-neighborhood of $\tau_0$. Then under Condition B(iii), we have,

(i) $\sup_{\tau \in T(\tau_0, u_n)} \frac{1}{n} \sum_{i=1}^n \zeta_i(\tau) \leq c_u \max\left\{\frac{\log p}{n}, u_n\right\}$, 

(ii) $\inf_{\tau \in \mathbb{R} : \Phi^*(\tau_0, \tau) \geq v_n} \frac{1}{n} \sum_{i=1}^n \zeta_i(\tau) \geq c_u v_n$,

with probability at least $1 - c_1 \exp(-c_2 \log p)$.

To proceed further, define for any $\tau$ the following set of random indices,

$$n_w := n_w(\tau_0, \tau) = \begin{cases} i \in \{1, \ldots, n\}; & \tau_0 < w_i \leq \tau, \text{ if } \tau > \tau_0, \\ i \in \{1, \ldots, n\}; & \tau \leq w_i < \tau_0, \text{ if } \tau \leq \tau_0. \end{cases}$$ (3.1)

Note that the cardinality of the random set $n_w$ is precisely the stochastic term controlled in Lemma 3.1, i.e., $|n_w| = \sum_{i=1}^n \zeta_i(\tau)$. This relation serves to provide bounds on several other stochastic terms considered in subsequent lemmas. The relationship between the cardinality of the random index set $n_w$ and the r.v.'s $\zeta_i(\tau), i = 1, \ldots, n$ has also been used by Kaul et al. (2017) in the context of graphical models with missing data.

**Lemma 3.2** Let $u_n$ be any non-negative sequence and let $n_w$ be the random set of indices as defined in (3.1). Also, let $T(\tau_0, u_n)$ be a $u_n$-neighborhood of $\tau_0$ as defined in Lemma 3.1.
Then under Condition B, we have for any fixed $\delta \in \mathbb{R}^p$ that,

\[(i)\quad \sup_{\tau \in T(\tau_0, u_n)} \left\| \frac{1}{n} \sum_{i \in \mathbb{N}_u} \delta^T x_i x_i^T \right\|_\infty \leq c_u c_{m1} \| \delta \|_2 \max \left\{ \frac{\log p}{n}, u_n \right\},\]

\[(ii)\quad \sup_{\tau \in T(\tau_0, u_n)} \frac{1}{n} \sum_{i \in \mathbb{N}_u} \delta^T x_i x_i^T \delta \leq c_u c_{m1} \| \delta \|_2^2 \max \left\{ \frac{\log p}{n}, u_n \right\},\]

\[(iii)\quad \sup_{\tau \in T(\tau_0, u_n)} \frac{1}{n} \left\| \sum_{i \in \mathbb{N}_u} \epsilon_i x_i^T \right\|_\infty \leq c_u c_{m2} \sqrt{\frac{\log p}{n}} \max \left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\},\]

with probability at least $1 - c_1 \exp(-c_2 \log p)$. Here $c_u > 0$ is a universal constant, and $c_{m1} = (\phi + \sigma_x + \sigma^2_x)$, $c_{m2} = (\sqrt{\sigma_x^2 \sigma_x^2} + \sigma_x \sigma_x)$ are model constants.

Finally in order to obtain the desired error bounds (2.8) and (2.9) we require restricted eigenvalue conditions on the gram matrix $\sum_{i=1}^n x_i x_i^T$. For any deterministic set $S \subset \{1, 2, ..., P\}$, define the collection $\mathcal{A}$ as,

$$\mathcal{A} = \left\{ \delta \in \mathbb{R}^p; \| \delta_{S^c} \|_1 \leq 3 \| \delta_S \|_1, \right\}.$$ \hspace{1cm} (3.2)

Then, Bickel et al. (2009) define the lower restricted eigenvalue condition as,

$$\inf_{\delta \in \mathcal{A}} \frac{1}{n} \sum_{i=1}^n \delta^T x_i x_i^T \delta \geq c_u \kappa \| \delta \|_2^2, \text{ for some constant } \kappa > 0.$$ \hspace{1cm} (3.3)

Other slightly weaker versions of this condition are also available in the literature such as the compatibility condition of Bühlmann and Van De Geer (2011), and the $\ell_q$ sensitivity of Gautier and Tsybakov (2011). In the setup of common random designs, it is also well established that condition (3.3) holds with probability converging to 1, see for e.g. Raskutti et al. (2010), and Rudelson and Zhou (2012), for Gaussian designs. In the subgaussian case, the plausibility of this condition is a consequence of a general result stated as Lemma B.2 in Appendix B. Under our high dimensional change point setup, we shall require versions of the restricted eigenvalue condition (3.3). In the following lemma, we shall show that all required conditions hold with probability converging to 1. Among other arguments, the proof of these conditions shall rely on Lemma B.2. In Lemma 3.3 below, the collection $\mathcal{A}$ in (3.2) applies for the set $S$ in Condition A.

**Lemma 3.3** (Restricted Eigenvalue Conditions): Let $u_n$, and $v_n$ be any non-negative sequences such that $v_n \geq c \log p / n$, $c > 0$. Let $T(\tau_0, u_n)$ be as in Lemma 3.1 and the set $\mathcal{A}$ as defined in (3.2) for $S$ given in Condition A. Furthermore, define the set $\mathcal{A}_2 = \left\{ \delta \in \mathbb{R}^p; \| \delta_{S^c} \|_1 \leq 3 \| \delta_S \|_1 + 3 \| \beta_0 - \gamma_0 \|_1 \right\}$, and let any $\tau \in \mathbb{R}$ be such that $\Phi^{-1}_\text{min}(\tau)s \log p / n = o(1)$. Then under Conditions A(i), A(ii), and B, and for $n$ sufficiently large, the following re-
Thus, the regression estimates obtained from (2.6) and (2.7) when \( \tau \) is sufficiently large, we have for \( n \) sufficiently large, and \( q = 1, 2 \),

\[
\|\hat{\beta}(\tau) - \gamma_0\|_q \leq c_u c_m \frac{1}{\Phi_{\min}(\tau)} s^{1/q} \sqrt{\frac{\log p}{n}},
\]

with probability at least \( 1-c_1 \exp(-c_2 \log p) \). The same bound holds for \( \|\hat{\gamma}(\tau) - \gamma_0\|_q, q = 1, 2 \).

(ii) When \( \Phi_{\min}(\tau_0) > 0 \), let \( u_n \) be any non-negative sequence satisfying \( u_n = o(\Phi_{\min}(\tau_0)) \). Also, let \( \mathcal{T}(\tau_0, u_n) \) be as defined in Lemma 3.1 and \( \lambda_1 = c_u c_m \max\{\sqrt{\log p/n}, \xi_n u_n\} \). Then for \( n \) sufficiently large, and \( q = 1, 2 \), the following uniform bound holds,

\[
\sup_{\tau \in \mathcal{T}(\tau_0, u_n)} \|\hat{\beta}(\tau) - \beta_0\|_q \leq c_u c_m \frac{1}{\Phi_{\min}(\tau_0)} s^{1/q} \max\left\{\sqrt{\frac{\log p}{n}}, \|\beta_0 - \gamma_0\|_2 u_n\right\},
\]

with probability at least \( 1-c_1 \exp(-c_2 \log p) \). The same uniform upper bound also holds for \( \sup_{\tau \in \mathcal{T}(\tau_0, u_n)} \|\hat{\gamma}(\tau) - \gamma_0\|_q, q = 1, 2 \).
Remark 4.1 As a direct consequence of Theorem 4.1, we obtain the rates of convergence of the regression estimates $\hat{\beta}^{(0)}, \hat{\gamma}^{(0)}$ from \textbf{Step 0} of \textbf{Algorithm 1}. Specifically, under the conditions of Theorem 4.1,

(i) When $\Phi_{\min}(\tau_0) = 0$,

$$\|\hat{\beta}^{(0)} - \gamma_0\|_q \leq c u c \Phi_{\min}(\tau_0) s^{1/q} \sqrt{\log p / n}, \quad q = 1, 2,$$

with probability at least $1 - c_1 \exp(-c_2 \log p)$. The same bound holds for $\|\hat{\gamma}^{(0)} - \gamma_0\|_q$, $q = 1, 2$.

(ii) When $\Phi_{\min}(\tau_0) > 0$, and $\left| \Phi(\tau^{(0)}) - \Phi(\tau_0) \right| \leq u_n^{(0)}$, we have,

$$\|\hat{\beta}^{(0)} - \beta_0\|_q \leq c u c \max \left\{ \sqrt{\log p / n}, \xi_n u_n^{(0)} \right\}, \quad q = 1, 2,$$

with probability at least $1 - c_1 \exp(-c_2 \log p)$. The same bound holds for $\|\hat{\gamma}^{(0)} - \gamma_0\|_q$, $q = 1, 2$.

In this case, since $s^{1/q} \xi_n u_n^{(0)} / \Phi(\tau_0)$ may diverge, these estimates are not guaranteed to be consistent. Nevertheless, (i) and (ii) above play an important role in deriving convergence rates of estimators from subsequent steps of Algorithm 1.

We now turn our attention to establishing selection and estimation results for estimates obtained from \textbf{Step 1} and \textbf{Step 2} of \textbf{Algorithm 1}. To achieve this goal, we require the following notations. For any $\tau \in \mathbb{R}, \beta, \gamma \in \mathbb{R}^p$, let

$$R_n(\tau, \beta, \gamma) = Q(\tau, \beta, \gamma) - Q(\tau_0, \beta, \gamma).$$

$$S_n(\tau, \beta, \gamma) = R_n(\tau, \beta, \gamma) + \mu(\|\Phi(\tau)\|_0 - \|\Phi(\tau_0)\|_0).$$

Also, for any non-negative $u_n$, and $v_n$, define the collection

$$\mathcal{H}(u_n, v_n) = \{ \tau \in \mathbb{R}; v_n \leq |\Phi(\tau) - \Phi(\tau_0)| \leq u_n \}$$

Additionally, for any non-negative sequence $u_n$, we also define the function,

$$F(u_n) = \begin{cases} 0 & \text{if } u_n/\Phi_{\min}(\tau_0) \to 0 \\ 1 & \text{otherwise} \end{cases}.$$  

Finally, in the following, we denote by $r_n := \max \left\{ \sqrt{s \log p / n}, \sqrt{\xi_n u_n^{(0)}} \right\} / \Phi_{\min}(\tau_0)$, in the case where $\Phi_{\min}(\tau_0) > 0$. Notice that $r_n$ is the $\ell_2$ rate of estimation error provided in Part(ii) of Remark 4.1. The following lemma provides a uniform lower bound of the expression $S_n(\tau, \beta, \gamma)$, over the collection $\mathcal{H}(u_n, v_n)$, that holds with high probability. This result shall lie at the heart of the argument used to obtain the main results of this article.

\textbf{Lemma 4.1} Suppose conditions $A$ and $B$ hold and let $u_n$ be any non negative sequence. Also, let $\hat{\beta}^{(0)}, \hat{\gamma}^{(0)}$ be estimates from \textbf{Step 0} of \textbf{Algorithm 1}. Then,
(i) When $\Phi(\tau_0) = 0$, for any $v_n > 0$, we have

$$\inf_{\tau \in \mathcal{H}(1,v_n)} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) \geq \mu - c_u c_m \frac{s \log p}{n \Phi^2_{\min}(\tau(0))}$$

with probability at least $1 - c_1 \exp(-c_2 \log p)$.

(ii) When $\Phi_{\min}(\tau_0) > 0$, for any $v_n \geq c \log p/n$, $c > 0$, we have,

$$\inf_{\tau \in \mathcal{H}(u_n,v_n)} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) \geq \xi_n^2 \left( c_u c_m v_n - c_u c_m \frac{s \log p}{n} - \frac{c_u c_m}{1 \vee \xi_n} \sqrt{\frac{s \log p}{n}} \max \left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\} - c_u c_m \frac{r_n^2}{1 \vee \xi_n^2} \max \left\{ \frac{s \log p}{n}, u_n \right\} - \frac{c_u \mu}{1 \vee \xi_n^2} F(u_n) \right)$$

with probability at least $1 - c_1 \exp(-c_2 \log p)$.

Our main result on rate of convergence of the estimates obtained from Algorithm 1 is stated in Theorem 4.2 below. While the complete proof of the theorem is given in the appendix, here we provide a sketch of the main idea behind the proof. We show that, for an appropriately chosen regularizer $\mu$, for any $v_n > 0$ (in the case where $\Phi(\tau_0) = 0$), or for any non-negative sequence $v_n$ slower in rate than those given in (2.8) (in the case where $\Phi_{\min}(\tau_0) > 0$), we shall show that,

$$\inf_{\tau; v_n \leq \Phi^*(\tau_0,\tau) \leq 1} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) > 0,$n sufficient large.

with probability at least $1 - c_1 \exp(-c_2 \log p)$. Upon noting that the global optimizer $\hat{\tau}^{(1)}$ by definition satisfies $S_n(\hat{\tau}^{(1)}, \hat{\beta}(0), \hat{\gamma}(0)) \leq 0$, we would have shown that the corresponding global optimizer $\hat{\tau}^{(1)}$ satisfies the relations given in (2.8). Along the way a sequence of recursions are required in order to sequentially sharpen the bound for the change point estimate. Supportive arguments are also required to show that the eventual bound is satisfied with probability at least $1 - c_1 \exp(-c_2 \log p)$. In this process, Remark 1 is quite helpful.

**Theorem 4.2** Suppose Conditions A and B hold and choose $\lambda_1 = c_u c_m \max\{\sqrt{\log p/n}, \xi_n u_n^{(0)}\}$, and $\mu = c_u c_m \left( s \log p/n l_n^2 \right)^{1/k^*}$, where $k^* = \max\{k, 2\}$. Then for $n$ sufficiently large, the optimizer $\hat{\tau}^{(1)}$ of Step 1 of Algorithm 1 satisfies the following relations.

(i) When $\Phi(\tau_0) = 0$, then $\Phi(\hat{\tau}^{(1)}) = 0$, with probability at least $1 - c_1 \exp(-c_2 \log p)$.

(ii) When $\Phi_{\min}(\tau_0) \geq c_u l_n$, then,

$$|\Phi(\hat{\tau}^{(1)}) - \Phi(\tau_0)| \leq t_n := c_u c_m \max\left\{ \frac{s \log p}{n}, \frac{1}{(1 \vee \xi_n^2)^2} \frac{s \log p}{n} \right\},$$

with probability at least $1 - c_1 \exp(-c_2 \log p)$.

The usefulness of Theorem 4.2 is apparent. Despite initializing Algorithm 1 with a $\tau^{(0)}$, which is in an $(s \log p/n l_n^2)^{1/k}$ neighborhood of $\tau_0$, for an nearly arbitrary $k \in [1, \infty)$, (any initial value that possesses ‘fractional information’ of $\tau_0$), the updated change point $\hat{\tau}^{(1)}$ lies in a near optimal neighborhood of $\tau_0$, irrespective of the value of $k$ (irrespective of the precision of the initial guess). The following theorem provides the rates of convergence of the regression coefficient estimates $\hat{\beta}^{(1)}$ and $\hat{\gamma}^{(1)}$ obtained from Step 2 of Algorithm 1.
Theorem 4.3 Suppose the model (1.1) in the case where a finite change point exists, i.e., \( \Phi_{\min}(\tau_0) > 0 \). Assume the conditions of Theorem 4.2 and choose \( \lambda_2 = c_u c_m \max \left\{ \sqrt{\log p/n}, \xi_n t_n \right\} \), where \( t_n \) is as defined in Theorem 4.2. Then, the estimates \( \hat{\beta}^{(1)} \) and \( \hat{\gamma}^{(1)} \) of Step 2 of Algorithm 1 satisfy,

\[
\begin{align*}
(i) \quad & \| \hat{\beta}^{(1)} - \beta_0 \|_q \leq c_u c_m s^{1/q} \frac{1}{\Phi_{\min}(\tau_0)} \max \left\{ \sqrt{\frac{\log p}{n}}, \xi_n t_n \right\}, \quad q = 1, 2, \\
(ii) \quad & \| \hat{\gamma}^{(1)} - \gamma_0 \|_q \leq c_u c_m s^{1/q} \frac{1}{\Phi_{\min}(\tau_0)} \max \left\{ \sqrt{\frac{\log p}{n}}, \xi_n t_n \right\}, \quad q = 1, 2,
\end{align*}
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \).

Remark 4.2 (Interpretation of the rates of Theorem 4.2 and Theorem 4.3) Note that under conditions of Theorem 4.2, and additionally assuming that \( \xi_n t_n \geq \xi_1 > 0 \), we have,

\[
|\Phi(\hat{\tau}^{(1)}) - \Phi(\tau_0)| \leq c_u c_m s \frac{\log p}{n},
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). This observation provides an intuitive statement, saying that an increasing jump size \( \xi_n \) can compensate for the location of the unknown change point moving toward the boundaries of \( \mathbb{R} \), in effect allowing \( \hat{\tau}^{(1)} \) of Algorithm 1 to approximate the unknown change point (if it exists) at a near optimal rate. In this case, under conditions of Theorem 4.3, the regression estimates of Step 2 become,

\[
\| \hat{\beta}^{(1)} - \beta_0 \|_q \leq c_u c_m s^{1/q} \frac{1}{\Phi_{\min}(\tau_0)} \max \left\{ \sqrt{\frac{\log p}{n}}, \xi_n \frac{s \log p}{n} \right\}, \quad q = 1, 2,
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). The same bound also holds for \( \| \hat{\gamma}^{(1)} - \gamma_0 \|_q \), \( q = 1, 2 \), with the same probability. The bound in the statement (4.3) again provides an interesting observation, where an increasing jump is leading to potentially counteract the precision of the regression estimate \( \hat{\beta}^{(1)} \). First note that, the bound in (4.3) can tolerate an increasing jump size \( \xi_n \) such that \( \xi_n s \sqrt{\log p/n} \to 0 \), while preserving optimality of the rate of convergence, i.e, yielding, \( \| \hat{\beta}^{(1)} - \beta_0 \|_2 \leq c_u c_m \Phi^{-1}(\tau_0) \sqrt{s \log p/n} \), with high probability. It is only when \( \xi_n \) increases faster than \( \sqrt{n/s^2 \log p} \) that it begins to harm the rate of convergence. This observation is surprising in that it suggests that an increasing jump size always benefits the change point estimate, whereas it benefits the regression coefficient estimates only when the jump size is increasing upto a certain rate. To the best of our knowledge, such a characterization of the effect of the jump size on parameter estimates, which holds only in the high dimensional case, has not been provided in the literature. The illustration in Figure 2 provides an intuitive understanding of this behavior.

![Diagram](attachment:Diagram.png)

**Figure 2:** Illustration of counteracting effect of jump size \( \xi_n \) on regression coefficient estimates
From Figure 2, observe that for any finite jump size, the best approximation that our analysis can provide is wherein the error is of order $s \log p/n$.\(^{g}\) Now the regression estimates of **Step 2** are computed based on the binary partition yielded by the change point estimate $\hat{\tau}^{(1)}$ of **Step 1**. Consequently, the data based on which the regression estimate $\hat{\beta}^{(1)}$ of $\beta_0$ is obtained, may be corrupted by as much as a fraction $O(s \log p/n)$ of observations where the true regression coefficient is $\gamma_0$. Thereby, the higher the jump size $\xi_0$, the more impact this small corruption will have on the estimate $\hat{\beta}^{(1)}$. The same argument also holds for the other binary partition. This provides an explanation of the rates observed in Theorem 4.3.

5. Implementation and Numerical Results

The three main objectives of this empirical study are, (i) to evaluate the overall performance of Algorithm 1, i.e., its ability to consistently estimate $\beta_0, \gamma_0$, and a finite $\tau_0$, and compare its performance to a full grid search approach, (ii) to numerically support the theoretically claimed statement, that the estimate $\hat{\tau}^{(1)}$ is insensitive to the quality of the initial guess $\tau^{(0)}$, and (iii) to evaluate the numerical performance of Algorithm 1 in detecting the ‘no change’ case, i.e., when $\Phi(\tau_0) = 0$.

5.1. Simulation setup

We consider the data generating process (1.1) where $\varepsilon_i, w_i$ and $x_i$ are drawn independently satisfying $\varepsilon_i \sim N(0, \sigma^2_\varepsilon)$, $w_i \sim U(0, 1)$.\(^{h}\) and $x_i \sim N(0, \Sigma)$. Here, $\Sigma$ is a $p \times p$ matrix with elements $\Sigma_{ij} = \rho^{(i-j)}$, $i, j = 1, ..., p$. We set, $\sigma_\varepsilon = 1$ and $\rho = 0.5$. The regression parameters of the model are set to be $\beta_0 = (1, 1, 1, ..., 0)^T_p$ and $\gamma_0 = (0_{1 \times 4}, 1, 1, 1, 0, ..., 0)^T_p$. The metrics of interest are bias and mean squared error of various estimates: For numerical experiments where $\Phi_{\text{min}}(\tau_0) > 0$, bias($\hat{\beta}$) = $\|E(\hat{\beta} - \beta_0)\|_2$, bias($\hat{\gamma}$) = $\|E(\hat{\gamma} - \gamma_0)\|_2$, bias($\hat{\tau}$) = $\|E(\hat{\tau} - \tau_0)\|_2$, mse($\hat{\beta}$) = $\|E(\hat{\beta} - \beta_0)^2\|_2$, mse($\hat{\gamma}$) = $\|E(\hat{\gamma} - \gamma_0)^2\|_2$, mse($\hat{\tau}$) = $E(\hat{\tau} - \tau_0)^2$, $\text{mse}(\Phi(\hat{\tau})) = E(\Phi(\hat{\tau}) - \Phi(\tau_0))^2$. For numerical experiments where $\Phi(\tau_0) = 0$, we report $\text{PrM} = E(1[\hat{\tau}^{(1)} = -\infty])$, i.e., the proportion of times where the ‘no change’ model is correctly identified. We shall report monte carlo approximations of these metrics based on 100 replications for each combination of model parameters. In the simulations where a finite change point, i.e., $0 < \tau_0 < 1$ is misidentified as ‘no change point’, i.e., $\hat{\tau}^{(1)} = -\infty$, (observed to occur sometimes when $\tau_0$ is near the boundaries of $(0, 1)$), we do the following operation to maintain fairness of comparisons of the above metrics. In case where $\tau_0 < 0.5$ and $\hat{\tau}^{(1)} = -\infty$, then we set $\hat{\tau}^{(1)} = 0, \hat{\beta}^{(1)} = 0_{p \times 1}$, and when $\tau_0 > 0.5$ and $\hat{\tau}^{(1)} = -\infty$, we set $\hat{\tau}^{(1)} = 1, \hat{\gamma}^{(1)} = 0_{p \times 1}$. Finally, we also report the metric *time*: the average (over replications) computation time.\(^{i}\) All computations are performed in the software R, R Core Team (2017). All lasso optimizations are performed with the R package ‘glmnet’, developed by Friedman et al. (2010). We perform two sets of simulations for all combinations of the parameters $n \in \{150, 250, 350\}$, $p \in \{25, 150, 250\}$. In the first simulation, we consider finite change points, with $\tau_0 \in \{0.169, 0.264, ..., 0.831\}$, (Equally spaced grid of 8 points between 0.169 to 0.831). This is referred to as **Simulation A** in the following. The second simulation considers the case of ‘no change’ in the model (1.1), i.e., $\tau_0 = 0$. This simulation is referred

---

\(^g\) This rate matches the fastest available in the literature

\(^h\) Since $w_i \sim U(0, 1)$, hence $\Phi(\tau) = \tau, \tau \in (0, 1)$.

\(^i\) CPU: Intel Xeon E5-2699 v3 @ 1.9 GHz, RAM: 128 GB
to as Simulation B in the following. Due to the absence of any comparative method that is able to detect the ‘no change’ case (to the best of our knowledge), we report only the results of our method for this simulation. Note that for each fixed \( p \), the total number of model parameters to be estimated is \( 2p + 1 \).

**Choice of tuning parameters:** The regularizer \( \lambda_1 \) and \( \lambda_2 \) of the Lasso optimizations of Step 0 and Step 2 of Algorithm 1 are chosen via a 5-fold cross validation, which is performed internally by the R package ‘glmnet’. The regularizer \( \mu \) of Step 1 of Algorithm 1 is chosen via the classical BIC criteria. Specifically, \( \hat{\mu} \) is performed internally by the R package ‘glmnet’. The regularizer \( \mu \) of Step 1 of Algorithm 1 is chosen via the classical BIC criteria. Specifically, \( \hat{\mu} \) is computed over a grid of values of \( \mu \). Then, the value of \( \mu \) of that minimizes the criteria,

\[
BIC(\mu) = \log \left( Q(\hat{\tau}(\mu), \hat{\beta}(\mu), \hat{\gamma}(\mu)) \right) + \frac{\log n}{n} ||\Phi(\hat{\tau}(\mu))||_0,
\]

is chosen. Here \( Q(\cdot, \cdot, \cdot) \) is the least squares loss, as defined in (2.1), and \( \hat{\beta}(\mu), \hat{\gamma}(\mu) \) represent regression coefficient estimates obtained on the binary partition given by \( \hat{\tau}(\mu) \).

In the following, we consider two schemes to choose the initializer \( \tau^{(0)} \) of Algorithm 1. The first is to set to \( w^{(0.5)} \), i.e., the 0.5\(^{th} \) empirical quantile of \( w = (w_1, \ldots, w_n)^T \). This is done to make the initializer equidistant from the two extremes of the support of \( w \). Note that, in the absence of any information on the unknown \( \tau_0 \), the choice \( \tau^{(0)} = w^{(0.5)} \) is a sensible choice for the initializer. This approach is represented as ‘Algorithm 1A’. As a second scheme, we choose the initializer \( \tau^{(0)} \) by setting it to one of values \( \{w^{(m)} : m = 0.25, 0.50, 0.75\} \), where \( w^{(m)} \) represents the \( m^{th} \) empirical quantile of \( w = (w_1, \ldots, w_n)^T \). This is done by first computing \( \hat{\beta}(\tau) \) and \( \hat{\gamma}(\tau) \) in (2.6) and (2.7) for each \( \tau = w^{(0.25)}, w^{(0.50)}, w^{(0.75)} \), and finally selecting \( \tau^{(0)} \) as the value that minimizes the least squares loss over these three choices. Note that the latter approach has an additional computational burden of two Lasso(\( n, p \)) optimizations in comparison to the former. This approach is represented as ‘Algorithm 1B’. Clearly, the initializer in Algorithm 1B will be a closer value to the unknown \( \tau_0 \) in comparison to the initializer of Algorithm 1A. This shall also help us numerically support our theoretical finding that Algorithm 1 is insensitive to the ‘quality’ of the initializer. Finally, we also implement the full grid search approach of Lee et al. (2016) in order to serve as a benchmark to compare the performance of the proposed estimates and also to illustrate the dramatic gains in computation time provided by our method. This approach is referred to as Full grid search in the following. For completeness, the Full grid search estimator of Lee et al. (2016) is described in the notation of this article in the following. The article of Lee et al. (2016) assumes the model \( y_i = x_i^T \beta_0 + x_i^T \eta_0 1[w_i \leq \tau_0] \), which is equivalent to the model (1.1) when \( \delta_0 = \gamma_0 \) and \( \eta_0 = \beta_0 - \gamma_0 \). Now, let \( \tilde{x}_i(\tau) = (x_i^T, x_i^T 1[w_i \leq \tau])^{T}_{2p 	imes 1} \), and the parameter \( \alpha = (\gamma, \beta - \gamma) \), where \( \beta_0, \gamma_0 \) are the true parameter coefficients of the model (1.1), then

\[
\hat{\alpha}(\tau) &= \arg \min_{\alpha \in \mathbb{R}^{2p}} \left\{ \frac{1}{n} \sum_{i=1}^{n} (y_i - \tilde{x}_i^T(\tau)\alpha)^2 + \lambda ||D(\tau)\alpha||_1 \right\}, \text{ for each } \tau \in T^*,
\]

\[
\hat{\tau} = \arg \min_{\tau \in T^*} \left\{ \frac{1}{n} \sum_{i=1}^{n} (y_i - \tilde{x}_i^T(\tau)\hat{\alpha}(\tau))^2 + \lambda ||D(\tau)\hat{\alpha}(\tau)||_1 \right\}
\]

(5.1)
Table 1: Numerical results of Algorithm 1A and 1B, and Full grid search for $n \in \{150, 250, 350\}$, $p \in \{25, 150, 250\}$, and $\tau_0 = 0.169$.

where $D(\tau) = \text{diag}\{\|\hat{x}^{(j)}(\tau)\|_n, j = 1, ..., 2p\}$, with $\hat{x}^{(j)}(\tau)$ representing the $j^{th}$ column of the design matrix $\hat{x}(\tau) = (\hat{x}_1(\tau), ..., \hat{x}_n(\tau))^{T}_{n \times 2p}$. In implementation of this estimator, the search space of the change point is restricted to $\tau \in T^* = \{w_1, ..., w_n\} \cap (0.1, 0.9)$.

5.2. Results and discussion

The bias and mean squared error (mse) of estimates obtained from Algorithms 1A, 1B, and Full grid search for Simulation A, for all combinations of $n \in \{150, 200, 250\}$, $p \in \{25, 150, 250\}$, and $\Phi(\tau_0) \in \{0.169, 0.67\}$ are presented in Table 1 and Table 2. All results provided are truncated at $10^{-4}$. Complete results of the simulation study including all cases for $\tau_0 \in \{0.169, 0.264, ..., 0.831\}$, are available in the supplementary materials of this article. To aid in interpretation, the results on bias are illustrated through Figures 3, 4, 5, 6 and 7. In particular, Figure 3 illustrates bias associated with the change point estimate, Figure 4 and Figure 5 illustrate the bias in $\hat{\beta}^{(1)}$, and $\hat{\gamma}^{(1)}$ respectively. In Figure 6 we illustrate the consistency of the proposed methodology and finally, in Figure 7 we depict the average computation time for the methods implemented in this simulation study. The results of Simulation B are reported in Table 3 This table reports the proportion of times the ‘no change’ model is correctly identified via the metric $PrM$ as described above.

Figure 3: Comparison of bias(\( \tau \)) for Algorithm 1A and 1B and Full grid search across values of \( \tau_0 \) for \( p = 250 \). Left panel: \( n = 150 \), Center panel: \( n = 250 \), Right panel: \( n = 350 \).
Figure 4: Comparison of bias(\(\hat{\beta}\)) for Algorithm 1A and 1B, and Full grid search across values of \(\tau_0\) for \(p = 250\). Left panel: \(n = 150\), Center panel: \(n = 250\), Right panel: \(n = 350\).

Figure 5: Comparison of bias(\(\hat{\gamma}\)) for Algorithm 1A and 1B, and Full grid search across values of \(\tau_0\) for \(p = 250\). Left panel: \(n = 150\), Center panel: \(n = 250\), Right panel: \(n = 350\).

Figure 6: Illustration of consistency of implemented methods with \(\tau_0 = 0.264\). Left panel: Algorithm 1A, Center panel: Algorithm 1B, and Right panel: Full grid search.
Figure 7: Comparison of computation time (in seconds) for **Algorithm 1A and 1B** and **Full grid search** across values of $n$ for $\tau_0 = 0.547$. Left panel: $p = 25$, Center panel: $p = 150$, Right panel: $p = 250$. Note that, these times are computed as averages over 100 replications of each method running in parallel over 12 cores. Running a single instance of any method is two to three times faster. Reported computation times include time taken to choose tuning parameters.

Distinguishable from the **Full grid search** approach of Lee et al. (2016). Second, it is also observed that the proposed **Algorithms 1A and 1B** are indistinguishable from each other in terms of the bias in the change point estimate. Recall that, Algorithm 1B was designed in a way so that the starting value is always closer to $\tau_0$ in comparison to **Algorithm 1A**. Despite a better initial value, no uniform improvement is observed in Algorithm 1B. This supports our theoretical result, that the quality of the initial value does not impact Algorithm 1, and it yields near optimal estimates with any initializing value containing any fractional information on the unknown change point. The bias results for the regression coefficient estimates depicted in Figures 4 and Figure 5 suggest that the proposed methodology yields a uniformly lower bias at all considered cases of $\tau_0$. One possible reason for this behavior is that the design variable in our methodology are constructed as $z_i = (z_i^{(1)}, z_i^{(2)})^T$ where $z_i^{(1)} = x_i$ and $z_i^{(2)} = 1[w_i \leq \tau_0]$, which are orthogonal to each other, in contrast, the design variables in the methodology of Lee et al. (2016), the design variables are constructed as $z_i^{(1)} = x_i$ and $z_i^{(2)} = 1[w_i \leq \tau_0]$, which may be highly correlated. It is also clear from Figure 6 that the in bias in change point estimates from **Algorithm 1A and 1B** and **Full grid search** progressively shrinks with increasing values of $n$, thereby illustrating the consistency of the proposed methodology. Finally, in Figure 7 we illustrate the dramatic differences in the overall computation times in the implementation of the compared approaches. In the largest considered data set, the average time for computation of **Algorithm 1A and 1B** was $\approx 3$ seconds, as opposed to the full grid search which required $\approx 200$ seconds to implement. Note that the reported computation times include the time taken for choosing all required tuning parameters for each method.

**Simulation B:** The results of **Simulation B** reported in Table 3 are in accordance with expectations. The proposed methods are able to detect the ‘no change’ scenario with $\approx 85\%$ accuracy in all considered cases. Selection consistency is also observed, i.e. the proportion of correct identifications is seen to increase with $n$. Finally, both **Algorithm**
1A and 1B are seen to provide the exact same results, which is again not surprising since the only difference in these two methods is the choice of the initial value.

6. Application

In this section, we apply our proposed methodology to the ‘Communities and Crime’ data set of Redmond and Baveja (2002), available publicly at https://archive.ics.uci.edu/ml/datasets/Communities+and+Crime. This data contains: (i) socio-economic data at a community level from across the entire United states, and is collected from the 1990 US Census, (ii) law enforcement data from the 1990 US Law Enforcement Management and Administrative Statistics survey, and (iii) crime data from the 1995 FBI Uniform Crime. The full data set contains 1994 observations and 128 variables. The dependent variable of interest is the total number of violent crimes per one hundred thousand population, which is calculated using the population and the sum of the crime variables that are considered violent crimes: murder, rape, robbery, and assault. The remaining variables are quantitative measurements on socio-economic variables such as the median (community level) income per household, percentage of people aged 16 and over who are employed, percentage of households with public assistance, percent of population who have immigrated within the last 10 years, amongst many others. This data was recently analyzed by Leonardi and Bühlmann (2016) for detecting and identifying change points in covariates when the change point(s) are modeled over locations. In this study we are interested in identifying changes in covariates when the change occurs through a change inducing variable. Specifically, we consider tow cases, (1) when the change inducing variable is assumed to be the population for the community, and (2) when the change inducing variable is assumed to be the median household income for the community, in an effort to investigate whether violent crime at a community level is influenced by distinct socio-economic factors below and above a certain threshold of population or the median household income, and also to estimate the threshold level at which such a transition occurs.

The full data set consists of \( n = 1994 \) observations and \( p = 128 \) variables, which have been normalized to \([0, 1]\) scale. The normalization process is described in the webpage whose link has been provided at the beginning of this section. This normalized data is pre-processed by deleting observations with any missing values, and by eliminating predictors that are highly correlated with other predictor variables. After the pre-processing, we obtain a filtered data set with \( n = 319 \) communities. The remaining data is then mean centered and scaled columnwise in order to remove the need for an intercept term in the regression, mainly to be consistent with model (1.1). Finally, predictor variables having a significant correlation with the change inducing variable have also been dropped from the analysis. This process yields a refined data set with \( p = 75 \) predictor variables (excluding the change inducing variable) in the case where the change inducing variable is ‘population’ and \( p = 77 \) in the case where the change inducing variable is ‘median income’.

We apply the proposed Algorithm 1 to the data under consideration with the initializer chosen as the 50\(^{th}\) percentile of the change inducing variable, i.e., Algorithm 1A described in Section 5. The regularizer’s \( \lambda_1, \lambda_2 \) and \( \mu \) are chosen via cross validation and the classical BIC criteria respectively, as described in Section 5. Table 4 summarizes estimation and variable selection results for the regression coefficients of the assumed model (1.1), in the
Table 4: Summary of analysis of ‘Communities and Crime’ data set. Change inducing variable (w): population, model size: n = 319, p = 75. Estimated change point is \( \hat{\tau}^{(1)} = 0.24 \), which is the 73\textsuperscript{rd} percentile of the population variable. The table lists all estimated non-zero regression coefficients truncated at \( 10^{-4} \).

case where the change inducing variable is ‘population’ and Table 5 summarizes the results of the case where the change inducing variable is the ‘median income’. In the first case with the change inducing variable as ‘population’, we find a change point estimate \( \hat{\tau}^{(1)} = 0.23 \) which is the 73\textsuperscript{rd} percentile of the population variable. A noteworthy observation in this case about the estimated pre and post coefficients \( \hat{\beta}^{(1)}, \hat{\gamma}^{(1)} \) from Table 4 is the near disjoint nature of the features influencing violent crime across the threshold \( \hat{\tau}^{(1)} \) of the population variable. In the second case, where the change inducing variable is ‘median income’ the proposed method detects ‘no change’ in the model, i.e., yields a ordinary linear regression model for this case.
Acknowledgement

We thank three anonymous referee’s for insightful comments and suggestions that led to a significant improvement to the results and presentation of the manuscript.

Appendix A: Proofs

Proof of Lemma 3.1: Let $\tau_1 > \tau_0$ be a boundary point on the right of $\tau_0$, such that $\Phi^*(\tau_0, \tau_1) = u_n$. Then recall that

$$
\zeta_i(\tau_1) = 1\{\tau_0 < u_i \leq \tau_1\}, \quad \Phi^*(\tau_0, \tau) = \Phi(\tau_1) - \Phi(\tau_0).
$$

Also, note that $p_n := E\zeta_i(\tau_1) = \Phi^*(\tau_0, \tau_1)$. Since $\zeta_i, i = 1, ..., n$ are Bernoulli r.v.’s, for any $s > 0$, the moment generating function is given by $E(\exp(s\zeta_i)) = q_n + p_n \exp(s)$, where $q_n = 1 - p_n$. Applying the Chernoff Inequality, we obtain,

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) > t + np_n\right) = P\left(e^{\sum_{i=1}^n s\zeta_i(\tau_1)} > e^{(st+sp_n)}\right) \leq e^{-s(t+np_n)}[q_n + p_n e^s]^n.
$$

Now in order to show,

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) \leq 1 \max\left\{\frac{\log p}{n}, u_n\right\}\right) \geq 1 - c_1 \exp(-c_2 \log p). \quad (A.1)
$$

We divide the argument into two cases. First, for any arbitrary constant $c_u > 0$, we let $\Phi^*(\tau_0, \tau_1) \geq c_u \log p/n$, upon choosing $t = n\Phi^*(\tau_0, \tau_1)$ we obtain,

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) > 2n\Phi^*(\tau_0, \tau_1)\right) \leq e^{[-2sn\Phi^*(\tau_0, \tau_1)][1 + (\Phi^*(\tau_0, \tau_1))(e^s - 1)]^n}.
$$

Using the deterministic inequality $(1 + x)^k \leq \exp(kx)$, for any $k, x > 0$, we obtain that

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) > 2n\Phi^*(\tau_0, \tau_1)\right) \leq e^{-2sn\Phi^*(\tau_0, \tau_1)}e^{(e^s - 1)n\Phi^*(\tau_0, \tau_1)} \leq e^{-c_2 \log p}.
$$

The inequality to the right follows by choosing $s = \log 2$, which maximizes the function $f(s) = 2s - e^s + 1$ and provides a positive value at the maximum, and by using the restriction $\Phi^*(\tau_0, \tau) \geq c_u \log p/n$. Next we let $\Phi^*(\tau_0, \tau) < c_u \log p/n$. Here choose $t = c_u \log p$ to obtain,

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) > c_u \log p + n\Phi^*(\tau_0, \tau_1)\right) \leq e^{-sc_u \log p - sn\Phi^*(\tau_0, \tau_1)}[1 + (\Phi^*(\tau_0, \tau_1))(e^s - 1)]q(A.2)
$$

Calling upon the inequality $(1 + x)^k \leq \exp(kx)$, for any $k, x > 0$, we can bound the RHS of (A.2) from above by $\exp \left[ - sc_u \log p + (e^s - s - 1) \log p \right]$. Now $s = \log(1 + c_u)$ provides a positive value at the maximum, since it maximizes $f(s) = (1 + c_u)s - e^s + 1$. Then for any $c_u > 0$, we obtain,

$$
P\left(\sum_{i=1}^n \zeta_i(\tau_1) > c_u \log p + n\Phi^*(\tau_0, \tau_1)\right) \leq e^{-c_2 \log p}.
$$
Upon combining both cases, (A.1) follows by noting $\Phi^*(\tau_0, \tau_1) = u_n$.

Now repeating the same argument for a fixed boundary point $\tau_2$ on the left of $\tau_0$, such that $\Phi(\tau_0) - \Phi(\tau_2) = u_n$, and applying a union bound we obtain,

$$
P\left( \max_{\tau \in \{\tau_1, \tau_2\}} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau) \leq c_u \max \left\{ \log \frac{p}{n}, u_n \right\} \right) \geq 1 - c_1 \exp(-c_2 \log p). \quad (A.3)
$$

It remains to show that (A.1) holds uniformly over $T(\tau_0, u_n)$. For this, we begin by noting that for any $\tau \in T(\tau_0, u_n)$, where $\tau > \tau_0$ we have $\zeta_i(\tau) = 1[w_i \in (\tau_0, \tau)] \leq 1[w_i \in (\tau_0, \tau_1)]$. Similarly for any $\tau \in T(\tau_0, u_n)$, where $\tau < \tau_0$ we have $\zeta_i(\tau) \leq 1[w_i \in [\tau_2, \tau_0)]$. Thus

$$
\sup_{\tau \in T(\tau_0, u_n)} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau) \leq \max_{\tau \in \{\tau_1, \tau_2\}} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau). \quad (A.4)
$$

Part (i) of this lemma follows by combining (A.4) with the bound in (A.3).

To prove Part (ii) we use a lower bound for sums of non-negative r.v.'s stated in Lemma B.3. This result was originally proved by Maurer (2003). For a fixed right boundary point $\tau_1 > \tau_0$ such that $\Phi(\tau_1) - \Phi(\tau_0) = v_n$, set $t = v_n/2$ in Lemma B.3. Then we have

$$
P\left( \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau_1) \leq \frac{v_n}{2} \right) \leq \exp\left( -nv_n \right) \leq c_1 \exp(-c_2 \log p),
$$

where the last inequality follows from $v_n \geq c_u \log p/n$. We obtain the same bound applying a similar argument for the left boundary point $\tau_2 < \tau_0$ such that $\Phi(\tau_0) - \Phi(\tau_2) = v_n$. Now applying an elementary union bound we obtain

$$
P\left( \min_{\tau \in \{\tau_1, \tau_2\}} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau) \geq c_u v_n \right) \geq 1 - c_1 \exp(-c_2 \log p). \quad (A.5)
$$

Finally to obtain uniformity over $\tau \in \{\tau; \Phi^*(\tau_0, \tau) \geq v_n\}$ note that for $\tau > \tau_0$, we have $\zeta_i(\tau) = 1[w_i \in (\tau_0, \tau)] \geq 1[w_i \in [\tau_0, \tau_1]]$ and for any $\tau < \tau_0$, we have $\zeta_i(\tau) = 1[w_i \in [\tau, \tau_0)] \geq 1[w_i \in [\tau_2, \tau_0)]$. This implies that

$$
\inf_{\{\tau; \Phi^*(\tau_0, \tau) \geq v_n\}} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau) \geq \min_{\tau \in \{\tau_1, \tau_2\}} \frac{1}{n} \sum_{i=1}^{n} \zeta_i(\tau). \quad (A.6)
$$

Part (ii) follows by combining (A.5) and (A.6). This complete the proof of Lemma 3.1. \(\square\)

**Proof of Lemma 3.2:** We begin with the proof of Part (i). Note that the RHS of the inequality in Part (i) is normalized by the $\ell_2$ norm of $\delta$. Hence, without loss of generality we can assume $\|\delta\|_2 = 1$. Now, the proof of this lemma relies on $|n_w| = \sum_{i=1}^{n} \zeta_i(\tau)$, where $\zeta_i(\tau)$ are as defined for Lemma 3.1. Note that if $|n_w| = 0$ then Lemma 3.2 holds trivially with probability 1, thus without loss of generality we shall assume that $|n_w| > 0$. Now, for any fixed $\tau \in T(\tau_0, u_n)$, we have

$$
\left\| \frac{1}{n} \sum_{i \in n_w} \delta^T x_i x_i^T \right\|_{\infty} \leq \frac{|n_w|}{n} \left\| \frac{1}{n_w} \sum_{i \in n_w} \delta^T x_i x_i^T \right\|_{\infty} \quad (A.7)
$$
The second key observation is that under Condition A(iv) and by properties of conditional expectations (see e.g. Lemma B.4), the conditional probability \( P_w(\cdot) = P(\cdot | w) \) can be bounded by treating \( w \) as a constant. Thus,

\[
P_w\left( \left\| \sum_{i \in n_w} \frac{\delta^T x_i x_i^T}{|n_w|} \right\|_\infty > t \right) \leq 6p \exp\left(-c_u |n_w| \min\left\{ \frac{t^2}{\sigma^2}, \frac{t}{\sigma^2} \right\} \right)
\]

where the above probability bound is obtained by an application of Part (ii) of Lemma 14 of Loh and Wainwright (2012): supplementary materials. This lemma is reproduced as Lemma B.1 in the Appendix. Now choosing \( t = c_u \max\left\{ \frac{\sigma^2}{\log p/|n_w|}, \sigma^2 \log p/|n_w| \right\} \) we obtain,

\[
P_w\left( \left\| \sum_{i \in n_w} \frac{\delta^T x_i x_i^T}{|n_w|} \right\|_\infty \leq \frac{|n_w|}{n} \left\| \delta^T \Sigma \right\|_\infty + c_u \max\left\{ \frac{\sigma^2}{\log p/|n_w|}, \sigma^2 \log p/|n_w| \right\} \right)
\]

\[
\geq 1 - c_1 \exp(-c_2 \log p).
\]

(A.8)

The result in (A.8) together with (A.7) yields,

\[
P_w\left( \left\| \frac{1}{n} \sum_{i \in n_w} \delta^T x_i x_i^T \right\|_\infty \leq \frac{|n_w|}{n} \left\| \delta^T \Sigma \right\|_\infty + c_u \max\left\{ \frac{\sigma^2}{\log p/|n_w|}, \sigma^2 \log p/|n_w| \right\} \right)
\]

\[
\geq 1 - c_1 \exp(-c_2 \log p).
\]

(A.9)

Taking expectations on both sides of the inequality (A.9) and observing that the RHS of the conditional probability (A.9) is free of \( w \), we obtain,

\[
P\left( \left\| \frac{1}{n} \sum_{i \in n_w} \delta^T x_i x_i^T \right\|_\infty \leq \frac{|n_w|}{n} \left\| \delta^T \Sigma \right\|_\infty + c_u \max\left\{ \frac{\sigma^2}{\log p/|n_w|}, \sigma^2 \log p/|n_w| \right\} \right)
\]

\[
\geq 1 - c_1 \exp(-c_2 \log p)
\]

(A.10)

On the other hand, we have by the result of Lemma 3.1 that with probability at least \( 1 - c_1 \exp(-c_2 \log p) \) that \( \sup_{\tau \in \mathcal{T}} |n_w|/n \leq c_u \max\{ \log p/n, u_n \} \). Also, it is straightforward to see that \( \left\| \delta^T \Sigma \right\|_\infty \leq c_u \phi \), for some constant \( c_u > 0 \). Thus with the same probability we have the bound,

\[
\sup_{\tau \in \mathcal{T}(\tau_0, u_n)} \frac{|n_w|}{n} \left\| \delta^T \Sigma \right\|_\infty \leq c_u \phi \max\left\{ \frac{\log p}{n}, u_n \right\}.
\]

(A.11)

By applying Part (i) of Lemma 3.1 we also have the following bound with probability at least \( 1 - c_1 \exp(-c_2 \log p) \),

\[
\sup_{\tau \in \mathcal{T}(\tau_0, u_n)} \frac{|n_w|}{n} \sqrt{\frac{\log p}{|n_w|}} \leq c_u \sqrt{\frac{\log p}{n}} \max\left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\} \leq c_u \max\left\{ \frac{\log p}{n}, u_n \right\}.
\]

(A.12)

The final inequality follows upon noting that if \( \sqrt{\log p/n} \sqrt{u_n} \geq u_n \) then \( u_n \leq \log p/n \). Finally also note that \( \sup_{\tau \in \mathcal{T}} (|n_w|/n)(\log p/|n_w|) \leq \log p/n \). Part (i) of the lemma follows.
by combining these results together with the bounds (A.11) and (A.12) in (A.10). The proofs of Part (ii) and Part (iii) are similar and are thus omitted.

**Proof of Lemma 3.3** To prove Part (i), first define \( z_i = x_i 1[w_i \leq \tau] \). Clearly \( z_i \) is also subgaussian with the same variance parameter as \( x_i \)'s, i.e., \( \sigma_x^2 \). Furthermore, since by assumption \( \Phi(\tau) > 0 \), thus \( \Sigma_z = \mathbb{E} z_i z_i^T = \Phi(\tau) \Sigma_x \), which implies that \( \lambda_{\min}(\Sigma_z) = \Phi(\tau) \lambda_{\min}(\Sigma_x) \geq \Phi(\tau) \kappa \). Similarly \( \lambda_{\max}(\Sigma_z) \leq \Phi(\tau) \phi \). Now applying Lemma B.2 we obtain

\[
\frac{1}{n} \sum_{\{i: w_i \leq \tau\}} \delta^T x_i x_i^T \delta = \frac{1}{n} \sum_{i=1}^{n} \delta^T z_i z_i^T \delta \geq c_w \kappa \Phi(\tau) \|\delta\|_2^2 - c_u \frac{1}{\Phi(\tau)} \log \frac{p}{n} \|\delta\|_1^2, \tag{A.13}
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Since \( \delta \in \mathbb{A} \), it is straightforward to see that \( \|\delta\|_2^2 \leq c_u s \|\delta\|_2^2 \). This together with Condition A(ii) yields Part (i). The proof of Part (ii) is quite similar. To prove Part (iii), we shall invoke the arguments seen in the proof of Lemma 3.2. Consider,

\[
\sup_{\tau \in T(\tau_0, u_n)} \sup_{\delta \in \mathbb{A}} \frac{1}{n} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta = \sup_{\tau \in T(\tau_0, u_n)} \frac{|n_w|}{n} \sup_{\delta \in \mathbb{A}} \frac{1}{|n_w|} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta \tag{A.14}
\]

Let \( P_w(\cdot) \) denote the conditional probability \( P(\cdot | w) \), where \( w = (w_1, \ldots, w_n)^T \). Then using Lemma B.2 we have

\[
P_w \left( \sup_{\delta \in \mathbb{A}} \frac{1}{|n_w|} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta \leq \frac{3\phi}{2} \|\delta\|_2^2 + c_u c_m \log \frac{p}{|n_w|} \|\delta\|_1^2 \right) \geq 1 - c_1 \exp(-c_2 \log p). \tag{A.15}
\]

Noting that the above probability on the RHS of (A.15) is free of \( w \), taking expectations on both sides we obtain,

\[
P \left( \sup_{\delta \in \mathbb{A}} \frac{1}{|n_w|} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta \leq \frac{3\phi}{2} \|\delta\|_2^2 + c_u c_m \log \frac{p}{|n_w|} \|\delta\|_1^2 \right) \geq 1 - c_1 \exp(-c_2 \log p). \tag{A.16}
\]

Recall from Lemma 3.1 that \( \sup_{\tau \in T(\tau_0, u_n)} |n_w|/n \leq c_u \max \{ \log p/n, u_n \} \), with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Combining this result with (A.16) and substituting into (A.14) we obtain

\[
\sup_{\tau \in T(\tau_0, u_n)} \sup_{\delta \in \mathbb{A}} \frac{1}{n} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta \leq c_u \phi \|\delta\|_2^2 \max \left\{ \log \frac{p}{n}, u_n \right\} + c_u c_m \frac{s \log p}{n} \|\delta\|_2^2
\]

\[
\leq c_u c_m \|\delta\|_2^2 \max \left\{ \frac{s \log p}{n}, u_n \right\}
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). This completes the proof of Part (iii). Proof of Part (iv) is based on similar arguments. First applying the same conditional argument as above, Part (i) of Lemma B.2 yields,

\[
P \left( \inf_{\delta \in \mathbb{A}_2} \frac{1}{|n_w|} \sum_{i \leq n_w} \delta^T x_i x_i^T \delta \geq \frac{\kappa}{2} \|\delta\|_2^2 - c_u c_m \log \frac{p}{|n_w|} \|\delta\|_1^2 \right) \geq 1 - c_1 \exp(-c_2 \log p). \tag{A.17}
\]
Since \( v_n \geq c \log p/n \), Part (ii) of Lemma 3.1 gives,

\[
\inf_{\tau \in \mathbb{R}; \Phi(\tau, u_n) \geq v_n} \inf_{\delta \in \mathbb{R}^2} \frac{1}{n} \sum_{i \in \mathbb{n}_u} \delta^T x_i x_i^T \delta \geq c_u \kappa \| \delta \|_2^2 v_n - c_u c_m \frac{\log p}{n} \| \delta \|_1,
\]

(A.18)

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). By the definition of the set \( A_2 \) together with the fact that \( \| \beta_0 - \gamma_0 \|_0 \leq s \), we also have

\[
\| \delta \|_2^2 \leq c_u s (\| \delta \|_2^2 + \| \beta_0 - \gamma_0 \|_2^2).
\]

(A.19)

Finally, substituting (A.19) in (A.18) we obtain

\[
\inf_{\tau \in \mathbb{R}; \Phi(\tau, u_n) \geq v_n} \inf_{\delta \in \mathbb{R}^2} \frac{1}{n} \sum_{i \in \mathbb{n}_w} \delta^T x_i x_i^T \delta \geq c_u \kappa \| \delta \|_2^2 v_n - c_u c_m \frac{\log p}{n} \| \delta \|_2^2 - c_u c_m \frac{\log p}{n} \| \beta_0 - \gamma_0 \|_2^2
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). This completes the proof of the lemma. \( \square \)

**Proof of Theorem 4.1:** To prove part (i), first note that when \( \Phi_{\text{min}}(\tau_0) = 0 \), the model (1.1) reduces to an ordinary linear regression model with regression coefficient \( \gamma_0 \). Thus for any \( \tau \in \mathbb{R} \), the estimates \( \hat{\beta}(\tau) \) and \( \hat{\gamma}(\tau) \) are ordinary Lasso estimates on the binary partitioned data \( (y_i, z_i) \), where \( z_i = x_i 1[w_i \leq \tau] \), and \( z_i = x_i 1[w_i > \tau] \), respectively. Also note that by assumption \( \Phi_{\text{min}}^{-1}((\tau) s \log p/n = o(1) \), thus the restricted eigenvalue condition of Part (i) and Part (ii) of Lemma 3.3 are applicable. The remaining arguments to prove the desired bounds are the same as typically used to derive bounds for Lasso estimates, such as those given in Chapter 6 of Bühlmann and Van De Geer (2011), these arguments are also similar to those to follow for the proof of Part (ii) and are thus omitted.

For the proof of Part (ii) where \( \Phi_{\text{min}}(\tau_0) > 0 \), we only prove the uniform bound for the error in estimate \( \| \hat{\beta}(\tau) - \beta_0 \|_q \). The proof for \( \| \hat{\gamma}(\tau) - \gamma_0 \|_q \) is nearly identical. First, for any \( \tau \in \mathcal{T}(\tau_0, u_n) \), note that by Lemma 3.2, we have,

\[
\sup_{\tau \in \mathcal{T}(\tau_0, u_n)} \left\| \frac{1}{n} \sum_{i; w_i \leq \tau} \varepsilon_i x_i^T \right\|_{\infty} \leq \left\| \frac{1}{n} \sum_{i; w_i \leq \tau} \varepsilon_i x_i^T \right\|_{\infty} \leq c_u c_m \sqrt{\frac{\log p}{n} + c_u c_m \max \left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\}} \leq c_u c_m \sqrt{\frac{\log p}{n}} \quad (A.20)
\]

with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Also we have for any \( \beta \in \mathbb{R}^p \) and \( \tau \in \mathbb{R} \),

\[
\frac{1}{n} \sum_{i; w_i \leq \tau} (y_i - x_i^T \beta)^2 = \frac{1}{n} \sum_{i; w_i \leq \tau} (y_i - x_i^T \beta_0 - x_i^T (\beta - \beta_0))^2 = \frac{1}{n} \sum_{i; w_i \leq \tau} \tilde{\varepsilon}_i^2 - \frac{2}{n} \sum_{i; w_i \leq \tau} \tilde{\varepsilon}_i x_i^T (\beta - \beta_0) + \frac{1}{n} \sum_{i; w_i \leq \tau} \| x_i^T (\beta - \beta_0) \|_2^2.
\]

(A.21)

Here \( \tilde{\varepsilon}_i = \varepsilon_i \), for \( i \in \{ i; w_i \leq \tau_0 \} \) and \( \tilde{\varepsilon}_i = \varepsilon_i - x_i^T (\beta_0 - \gamma_0) \) for \( i \in \{ i; w_i > \tau_0 \} \). Now by the definition of \( \hat{\beta}(\tau) \), it follows that

\[
\frac{1}{n} \sum_{i; w_i \leq \tau} (y_i - x_i^T \hat{\beta}(\tau))^2 + \lambda_1 \| \hat{\beta}(\tau) \|_1 \leq \frac{1}{n} \sum_{i; w_i \leq \tau} (y_i - x_i^T \beta_0)^2 + \lambda_1 \| \beta_0 \|_1.
\]

(A.22)
Applying (A.21) in (A.22) and carrying out some algebraic operations we get

\[
\frac{1}{n} \sum_{i:w_i \leq \tau} \|x_i^T(\hat{\beta}(\tau) - \beta_0)\|^2 + \lambda_1 \|\hat{\beta}(\tau)\|_1
\]

\[
\leq \lambda_1 \|\beta_0\|_1 + \frac{2}{n} \sum_{i:w_i \leq \tau} \varepsilon_i x_i(\hat{\beta}(\tau) - \beta_0) + \frac{2}{n} \sum_{\tau_0 < w_i \leq \tau} (\beta_0 - \gamma_0)x_i x_i^T(\hat{\beta}(\tau) - \beta_0)
\]

\[
\leq \frac{2}{n} \sum_{i:w_i \leq \tau} \varepsilon_i x_i \|\hat{\beta}(\tau) - \beta_0\|_1 + \frac{2}{n} \sum_{i \in n_w} (\beta_0 - \gamma_0)x_i x_i^T \|\hat{\beta}(\tau) - \beta_0\|_1 + \lambda_1 \|\beta_0\|_1
\]

\[
\leq c_u c_m \|\beta_0 - \gamma_0\|_2 \max \left\{ \frac{\log p}{n}, u_n \right\} \|\hat{\beta}(\tau) - \beta_0\|_1 + c_u c_m \max \sqrt{\frac{\log p}{n}} \|\hat{\beta}(\tau) - \beta_0\|_1 + \lambda_1 \|\beta_0\|_1
\]

\[
\leq \lambda \|\hat{\beta}(\tau) - \beta_0\|_1 + \lambda_1 \|\beta_0\|_1.
\]

(A.23)

Here \( \lambda = c_u c_m \max \left\{ \sqrt{\frac{\log p}{n}}, \|\beta_0 - \gamma_0\|_2 u_n \right\} \). The first term of the second to last inequality follows from (A.20) and the second term from Part (i) of Lemma 3.2. The bound (A.23) holds uniformly over \( \tau \in \mathcal{T}(\tau_0, u_n) \) with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Observe that the first term on the LHS of inequalities (A.23) is nonnegative, therefore \( \lambda_1 \|\hat{\beta}\|_1 \leq \lambda \|\hat{\beta} - \beta_0\|_1 + \lambda_1 \|\beta_0\|_1 \). Choosing \( \lambda_1 \geq 2\lambda \) leads to the inequality \( \|\hat{\beta}_S\|_1 \leq 3\|\hat{\beta}_S - \beta_0_S\|_1 \), by elementary triangle inequalities, see for e.g. Lemma 6.3 of Bühlmann and Van De Geer (2011). Thus \( \delta = \hat{\beta} - \beta_0 \in \mathcal{A} \) and thus the first three inequalities of Lemma 3.3 are now applicable. From (A.23) we obtain,

\[
\frac{2}{n} \sum_{i:w_i \leq \tau_0} \|x_i^T(\hat{\beta}(\tau) - \beta_0)\|^2 - \frac{2}{n} \sum_{i \in n_w} \|x_i^T(\hat{\beta}(\tau) - \beta_0)\|^2 \leq 3\lambda_1 \|\hat{\beta}(\tau) - \beta_0\|_1
\]

\[
\leq 3\sqrt{s} \lambda_1 \|\hat{\beta}(\tau) - \beta_0\|_2 \quad \text{(A.24)}
\]

Bounding the terms on the LHS of (A.24) by applying Part (i) and (iii) of Lemma 3.3 together with the assumption \( u_n = o(\Phi(\tau_0)) \), yields

\[
c_u c_m \Phi(\tau_0) \|\hat{\beta} - \beta_0\|^2 \leq 3\sqrt{s} \lambda_1 \|\hat{\beta} - \beta_0\|_2
\]

This directly implies \( \|\hat{\beta}(\tau) - \beta_0\|_2 \leq c_u c_m \sqrt{s} \lambda_1 \). The \( \ell_1 \) bound \( \|\hat{\beta}(\tau) - \beta_0\|_1 \leq \sqrt{s} \|\hat{\beta} - \beta_0\|_2 \), follows from the previously shown result that \( \hat{\beta}(\tau) - \beta_0 \in \mathcal{A} \). To complete the proof of Part (ii), note that all bounds in the above arguments hold uniformly over \( \mathcal{T}(\tau_0, u_n) \), consequently the final bound holds uniformly over \( \mathcal{T}(\tau_0, u_n) \). \( \square \)
Proof of Lemma 4.1: We begin with proving Part (i), where $\Phi(\tau_0) = 0$, in this case, for any $\tau \in \mathbb{R}$, we have

$$nR_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) = \sum_{i; w_i \leq \tau} (y_i - x_i^T \hat{\beta}(0))^2 + \sum_{i; w_i > \tau} (y_i - x_i^T \hat{\gamma}(0))^2 - \sum_{i; w_i > \tau_0} (y_i - x_i^T \hat{\gamma}(0))^2$$

$$= \sum_{i; w_i \leq \tau} (y_i - x_i^T \hat{\beta}(0))^2 - \sum_{i; \tau_0 < w_i \leq \tau} (y_i - x_i^T \hat{\gamma}(0))^2$$

$$= \sum_{i; \tau_0 \leq \tau} (\hat{\beta}(0) - \gamma_0)^T x_i x_i^T (\hat{\beta}(0) - \gamma_0) - \sum_{i; \tau_0 < \tau} (\hat{\gamma}(0) - \gamma_0)^T x_i x_i^T (\hat{\gamma}(0) - \gamma_0)$$

$$- 2 \sum_{i; \tau_0 \leq \tau} \varepsilon_i x_i^T (\hat{\beta}(0) - \gamma_0) + 2 \sum_{i; \tau_0 \leq \tau} \varepsilon_i x_i^T (\hat{\gamma}(0) - \gamma_0)$$

$$\geq - \sum_{i \in A_n} (\hat{\gamma}(0) - \gamma_0)^T x_i x_i^T (\hat{\gamma}(0) - \gamma_0) - 2 \sum_{i; \tau_0 \leq \tau} \varepsilon_i x_i^T (\hat{\beta}(0) - \gamma_0)$$

$$+ 2 \sum_{i; \tau_0 \leq \tau} \varepsilon_i x_i^T (\hat{\gamma}(0) - \gamma_0) \quad (A.25)$$

Now, by the result in Remark 4.1, we have that $\|\hat{\beta}(0) - \gamma_0\|_2, \|\hat{\gamma}(0) - \gamma_0\| \leq c_u c_m \sqrt{s \log p/n \Phi_{\min}(\tau(0))}$, with probability at least $1 - c_1 \exp(-c_2 \log p)$. Additionally from the proof of Theorem 4.1, it has also been shown that $\hat{\beta}(0) - \gamma_0$ and $\hat{\gamma}(0) - \gamma_0$ lie in the set $\mathcal{A}$ of (3.2), with the same probability. Thus the bounds of Lemma 3.2 are applicable. Substituting these bounds in (A.25), for any $v_n > 0$, we obtain uniformly over $\mathcal{H}(1, v_n)$ that,

$$\inf_{\tau \in \mathcal{H}(u_n, v_n)} R_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) \geq -c_u c_m \frac{s \log p}{n \Phi_{\min}(\tau(0))} - c_u c_m \frac{s \log p}{n \Phi_{\min}(\tau(0))}$$

Finally, recall that $S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) = R_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) + \mu(\|\Phi(\tau)\|_0 - \|\Phi(\tau_0)\|_0)$, and since in this case $\|\Phi(\tau)\|_0 = 0$, and for any $\tau \in \mathcal{H}(1, v_n)$, we have $\|\Phi(\tau)\|_0 = 1$ (since $v_n > 0$), hence the statement of Part (i) follows directly.

To prove Part (ii), where $\Phi(\tau_0) > 0$, we divide the argument into two cases. First consider the case where $\tau \in \mathcal{H}(u_n, v_n)$, with $\tau \geq \tau_0$, here,

$$nR_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) = nQ(\tau, \hat{\beta}(0), \hat{\gamma}(0)) - nQ(\tau_0, \hat{\beta}(0), \hat{\gamma}(0))$$

$$= \sum_{i \in \tau_0 \leq \tau} (y_i - x_i^T \beta)^2 - \sum_{i \tau_0 < \tau} (y_i - x_i^T \gamma)^2 \quad (A.26)$$

Recall by construction of model (1.1), $\varepsilon_i = y_i - x_i^T \gamma_0$, for $i; w_i > \tau_0$. Using this relation in (A.26) and performing some algebraic manipulation we have that

$$R_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) = \frac{1}{n} \sum_{i \in n_w} (\hat{\beta}(0) - \gamma_0)^T x_i x_i^T (\hat{\beta}(0) - \gamma_0) - \frac{1}{n} \sum_{i \in n_w} (\hat{\gamma}(0) - \gamma_0)^T x_i x_i^T (\hat{\gamma}(0) - \gamma_0)$$

$$- \frac{2}{n} \sum_{i \in n_w} \varepsilon_i x_i^T (\hat{\beta}(0) - \gamma_0) + \frac{2}{n} \sum_{i \in n_w} \varepsilon_i x_i^T (\hat{\gamma}(0) - \gamma_0)$$

$$:= T1 + T2 + T3 + T4 \quad (A.27)$$
Substituting bounds for term (T1)-(T4) given in Lemma 4.1 (stated after this proof), we obtain,

\[
\inf_{\tau \in \mathcal{H}(u_n,v_n)} R_n(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) \geq c_u c_m c_n^2 v_n - c_u c_m c_n^2 s \log \frac{p}{n} - c_u c_m \xi_n \sqrt{\frac{s \log \frac{p}{n}}{n}} \max \left\{ \sqrt{\frac{\log \frac{p}{n}}{n}}, \sqrt{u_n} \right\} - c_u c_m r_n^2 \max \left\{ \frac{s \log \frac{p}{n}}{n}, u_n \right\}.
\]

Now, note that for any \(\tau \in \mathbb{R}\), we have that \(\|\Phi(\tau)\|_0 - \|\Phi(\tau_0)\|_0 \leq 1\). Also, when \(u_n/\Phi(\tau_0) \to 0\), for any \(\tau \in \mathcal{H}(u_n,v_n)\), the quantities \(\Phi(\tau_0)\) and \(\Phi(\tau)\) will have the same sign, consequently \(\|\Phi(\tau)\|_0 - \|\Phi(\tau_0)\|_0 = 0\). In effect, we have for any \(\tau \in \mathcal{H}(u_n,v_n)\), that \(\|\Phi(\tau)\|_0 - \|\Phi(\tau_0)\|_0 \leq F(u_n)\). Using this relation in the definition of \(S(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)})\), together with the assumption that \(\xi_n > c_u\) we obtain,

\[
\inf_{\tau \in \mathcal{H}(u_n,v_n)} S_n(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) \geq \xi_n^2 \left( c_u c_m v_n - c_u c_m \frac{s \log \frac{p}{n}}{n} - c_u c_m \xi_n \sqrt{\frac{s \log \frac{p}{n}}{n}} \max \left\{ \sqrt{\frac{\log \frac{p}{n}}{n}}, \sqrt{u_n} \right\} \right)
- c_u c_m r_n^2 \max \left\{ \frac{s \log \frac{p}{n}}{n}, u_n \right\} - c_u c_m c_n^2 F(u_n),
\]

with probability at least \(1 - c_1 \exp(-c_2 \log p)\). This completes the proof of this lemma. \(\square\)

**Lemma 4.1** Suppose the conditions of Lemma 4.1 and let the terms T1, T2, T3 and T4 be as defined in (A.27). Then for \(n\) sufficiently large, we have the following bounds,

(i) \(\inf_{\tau \in \mathcal{H}(u_n,v_n)} |T1| \geq c_u c_m c_n^2 v_n - c_u c_m c_n^2 s \log \frac{p}{n}\)

(ii) \(\sup_{\tau \in \mathcal{H}(u_n,v_n)} |T2| \leq c_u c_m r_n^2 \max \left\{ \frac{s \log \frac{p}{n}}{n}, u_n \right\}\)

(iii) \(\sup_{\tau \in \mathcal{H}(u_n,v_n)} |T3| \leq c_u c_m c_n^2 \xi_n \sqrt{\frac{s \log \frac{p}{n}}{n}} \max \left\{ \sqrt{\frac{\log \frac{p}{n}}{n}}, \sqrt{u_n} \right\}\)

(iv) \(\sup_{\tau \in \mathcal{H}(u_n,v_n)} |T4| \leq c_u c_m r_n^2 \sqrt{\frac{s \log \frac{p}{n}}{n}} \max \left\{ \sqrt{\frac{\log \frac{p}{n}}{n}}, \sqrt{u_n} \right\}\)

with probability at least \(1 - c_1 \exp(-c_2 \log p)\).

**Proof of Lemma 4.1:** Consider the term \(T1 = n^{-1} \sum_{i \in n_w} (\hat{\beta}^{(0)} - \gamma_0)^T x_i x_i^T (\hat{\beta}^{(0)} - \gamma_0)\). First, recall from the proof of Theorem 4.1 that \(\hat{\beta}^{(0)} - \beta_0 \in A\), with probability at least \(1 - c_1 \exp(-c_2 \log p)\). Thus, as described in Remark 3.1, we have that \(\delta = \hat{\beta}^{(0)} - \gamma_0 = \hat{\beta}^{(0)} - \beta_0 + \beta_0 - \gamma_0 \in A_2\) with the same probability. Now applying Part (iv) of Lemma 3.3 we obtain,

\[
\inf_{\tau \in \mathcal{H}(u_n,v_n)} \frac{1}{n} \sum_{i \in n_w} \delta^T x_i x_i^T \delta \geq c_u c_m v_n \|\delta\|^2_2 - c_u c_m \frac{s \log \frac{p}{n}}{n} (\|\delta\|^2_2 + \xi_n^2)
\]

with probability at least \(1 - c_1 \exp(-c_2 \log p)\). Applying the algebraic inequality, \(\|\delta_1 + \delta_2\|^2_2 \geq \|\delta_1\|^2_2 + \|\delta_2\|^2_2 - 2\|\delta_1\|_2 \|\delta_2\|_2\) which is applicable for any \(\delta_1, \delta_2 \in \mathbb{R}^p\), we obtain,
\[ \|\hat{\beta}^{(0)} - \beta_0 + \beta_0 - \gamma_0\|^2 \geq r_n^2 + \xi_n^2 - 2r_n\xi_n. \] Now, by definition of \( r_n \), we also have that \( r_n = o(1)\xi_n \), thus \( \|\hat{\beta}^{(0)} - \beta_0 + \beta_0 - \gamma_0\|^2 \geq c_u\xi_n^2 \), for \( n \) large. Similarly, using the inequality \( \|\delta_1 + \delta_2\|^2 \leq \|\delta_1\|^2 + \|\delta_2\|^2 + 2\|\delta_1\|\|\delta_2\| \), we can show that for \( n \) large, \( \|\hat{\beta}^{(0)} - \beta_0 + \beta_0 - \gamma_0\|^2 \leq c_u\xi_n^2 \). Substituting these bounds back in (A.28) we obtain the result of Part (i). Next consider Part (ii), where we have \( T^2 = n^{-1} \sum_{i \in n_u} \hat{e}_i (\gamma^{(0)} - \gamma) x_i x_i^T (\gamma^{(0)} - \gamma) = 0 \). Recall from the proof of Theorem 4.1, \( \hat{\gamma}^{(0)} - \gamma \in \mathcal{A} \). Now applying Part (iii) of Lemma 3.3 we obtain,
\[ \sup_{\tau \in \mathcal{H}(u_n, v_n)} \frac{1}{n} \sum_{i \in n_u} \hat{e}_i x_i^T (\hat{\gamma}^{(0)} - \gamma) \leq c_u c_m r_n \max \left\{ \frac{s \log p}{n}, u_n \right\} \]
with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). This proves Part (ii). The proof of Part (iii) follows by an application of Part (iii) of Lemma 3.2 i.e.,
\[ \sup_{\tau \in \mathcal{H}(u_n, v_n)} \left| \frac{1}{n} \sum_{i \in n_u} \hat{e}_i x_i^T (\hat{\beta}^{(0)} - \beta_0) \right| \leq \sup_{\tau \in \mathcal{H}(u_n, v_n)} \left\| \frac{1}{n} \sum_{i \in n_u} \hat{e}_i x_i^T \right\|_1 \]
\[ \leq \sup_{\tau \in \mathcal{H}(u_n, v_n)} \left\| \frac{1}{n} \sum_{i \in n_u} \hat{e}_i x_i^T \right\|_\infty \sqrt{s} (\|\hat{\beta}^{(0)} - \beta_0\|_2 + \|\beta_0 - \gamma_0\|_1) \]
\[ \leq c_u c_m r_n \sqrt{\frac{s \log p}{n}} \max \left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\} + c_u c_m \xi_n \sqrt{\frac{s \log p}{n}} \max \left\{ \sqrt{\frac{\log p}{n}}, \sqrt{u_n} \right\} \]
with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). This proves Part (iii). The proof of Part (iv) is very similar and is thus omitted.

**Proof of Theorem 4.2:** First consider Part (i), where \( \Phi(\tau_0) = 0 \). Applying Part (i) of Lemma 4.1 for any \( v_n > 0 \), we have,
\[ \inf_{\tau \in \mathcal{H}(1, v_n)} S_n(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) \geq \mu - c_u c_m \frac{s \log p}{n \Phi_{\min}(\tau^{(0)})} \]
with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Recall the choice of \( \mu = c_u c_m \left( \frac{s \log p}{n l_n^2} \right)^{1/k^*} \), and the initializing condition \( \Phi_{\min}(\tau^{(0)}) \geq c_u v_n \). Consequently, \( \inf_{\tau \in \mathcal{H}(1, v_n)} S_n(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) \geq 0 \), for \( n \) sufficiently large, with the same probability. This implies that \( \hat{\tau}^{(1)} \notin \mathcal{H}(1, v_n) \) for any \( v_n > 0 \). Thereby proving that \( \Phi(\tau^{(1)}) = 0 \) is the only remaining possibility with the same probability. This completes the proof of Part (i).

To prove Part (ii), for any \( v_n \geq s \log p/n \), we apply Part (ii) of Lemma 4.1 on the set \( \mathcal{H}(1, v_n) \), to obtain,
\[ \inf_{\tau \in \mathcal{H}(1, v_n)} S_n(\tau, \hat{\beta}^{(0)}, \hat{\gamma}^{(0)}) \geq \xi_n^2 \left( c_u c_m v_n - c_u c_m \frac{s \log p}{n} \right) \]
\[ - c_u c_m \left( \frac{r_n^2}{1 \vee \xi_n} - \frac{c_u \mu}{1 \vee \xi_n} \right), \]
with probability at least \( 1 - c_1 \exp(-c_2 \log p) \). Note that, by Condition A(ii) we have that \( (s/l_n^2) v_n^{(0)} = o(1) \). Then, upon choosing,
\[ v_n \geq v^*_n := c_u c_m \max \left\{ \frac{s \log p}{n}, \frac{1}{1 \vee \xi_n} \left( \frac{s \log p}{n l_n^2} \right)^{1/k^*} \right\} \]
33
for some $c_u > 0$, we have that $\inf_{r \in \mathcal{H}(1,v_n)} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) > 0$, for $n$ sufficiently large. This follows by the choice of $\mu = (s \log p/n^2)k^*$, and by $r_n^2/\xi_n^2 < v_n^*$, which in turn follows from Condition A(iii). This implies that $\hat{\tau}(1) \notin \mathcal{H}(1,v_n)$, i.e., $|\Phi(\hat{\tau}(1)) - \Phi(\tau_0)| \leq v_n^*$ with probability at least $1 - c_1 \exp(-c_2 \log p)$. Note that if $\frac{1}{\sqrt{\xi_n}} \left( \frac{s \log p}{m_n^2} \right)^{1/k^*} \leq \frac{s \log p}{n}$, then the result is already proved. Else, reset $u_n = v_n^*$ and reapply the above argument for any $v_n \geq s \log p/n$, to obtain,

$$\inf_{\tau \in \mathcal{H}(u_n,v_n)} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) \geq \xi_n^2 \left( c_u c_m v_n - c_u c_m \frac{s \log p}{n} - \frac{c_u c_m}{1 + \xi_n} \sqrt{\frac{s \log p}{n} \max \left\{ \sqrt{\frac{s \log p}{n^2}}, u_n \right\} } \right.$$ 

we obtain that for $n$ large, $\inf_{r \in \mathcal{H}(u_n,v_n)} S_n(\tau, \hat{\beta}(0), \hat{\gamma}(0)) > 0$, with probability at least $1 - c_1 \exp(-c_2 \log p)$. Consequently $\hat{\tau}(1) \notin \mathcal{H}(u_n,v_n)$, i.e., $|\Phi(\hat{\tau}(1)) - \Phi(\tau_0)| \leq v_n^*$. Note that, by using the above recursive argument, we have tightened the desired rate at each step. As seen earlier, if the second term of the maximum expression is smaller than the first, then the proof is done. Else, continuing these recursions, by resetting $u_n$ to the bound of the previous recursion, and applying Part (ii) of Lemma 4.1, we can obtain for the $m^{th}$ recursion that

$$|\Phi(\hat{\tau}(1)) - \Phi(\tau_0)| \leq c_u c_m \max \left\{ \frac{s \log p}{n}, \frac{1}{1 + \xi_n} \left( \frac{s \log p}{n^2} \right)^{a_m} \right\},$$

with $a_1 = b_1 = 1/k^*$. Note that, despite the recursions in the above argument, the probability of the bound obtained after every recursion is maintained to be at least $1 - c_1 \exp(-c_2 \log p)$, this follows from Remark 1. To finish the proof, note that $k^* \in [2,3]$, $a_m = 1/2 + a_{m-1}/2$, $\forall m$ and when $k^* > 3$, $a_m = 1/2 + a_{m-1}/2$, for $m$ large enough. Finally, if we continue the above recursions an infinite number of times we obtain $a_\infty = \sum_{m=1}^{\infty} 1/2^m = 1$, and $b_\infty = 1 + \sum_{m=1}^{\infty} 1/2^m = 2$. This finishes the proof of this theorem. □.

Remark 1 (Observation utilized in the proof of Theorem 4.2): The proof of Theorem 4.2 relies on a recursive application of Lemma 4.1. this in turn requires a recursive application of the bounds of Lemma .1, where the probability of all bounds holding simultaneously at each recursion being at least $1 - c_1 \exp(-c_2 \log p)$. Despite these recursions (potentially infinite) the result from the final recursion continues to hold with probability at least $1 - c_1 \exp(-c_2 \log p)$. To see this, let $u_n \to 0$ be any positive sequence and let $\{a_j\} \to a_\infty$, $j \to \infty$, $0 < a_j \leq 1$, be any strictly increasing sequence over $j = 1, 2, \ldots$. Then define sequences $u_n^j = u_n^{j+1}$, $j = 1, 2, \ldots$. Here note that $u_n^{j+1} = o(u_n^j)$, $j = 1, \ldots$, i.e., each
sequence converges to zero faster than the preceding one. Let $E_{u^1}, E_{u^2}, \ldots$ be events, each with probability $1 - c_1 \exp(-c_2 \log p)$, on which the upper bounds of Lemma 1 hold for each $u_{n_1}^1, u_{n_2}^2, \ldots$ respectively. Clearly, on the intersection of events $E_{u^1} \cap E_{u^2} \cap \ldots$, all upper bounds of Lemma 1 hold simultaneously over any sequence $u_n^j$, $j = 1, \ldots, \infty$. Now, note that by the construction of these sequences, and that these are all upper bounds, the following containment holds $E_{u^1} \supseteq E_{u^2} \supseteq \ldots \supseteq E_{u^\infty}$. This implies that on the event $E_{u^\infty}$ all bounds of Lemma 1 hold simultaneously for any sequence $\{u_n^j\}$, $j = 1, \ldots, \infty$. Here $E_{u^\infty}$ represents the set corresponding to the sequence $u_n^\infty = u_n^j$. Also, by a single application of Lemma 1, $P(E_{u^\infty}) \geq 1 - c_1 \exp(-c_2 \log p)$. The same argument can be made for the lower bound of Lemma 1, with the direction of the containment switched.

**Proof of Theorem 4.3:** Recall that the result of Part (ii) of Theorem 4.1 is a uniform result over the set $T(\tau_0, u_n)$. The proof of this theorem is now a direct application of Part (ii) of Theorem 4.1, since by the result of Theorem 4.2, we have that $\hat{\tau}^{(1)} \in T(\tau_0, t_n)$, with probability at least $1 - c_1 \exp(-c_2 \log p)$. □

**Appendix B: Auxiliary lemma’s**

Here we restate without proof the technical lemma’s from the literature which have been used in the analysis presented in this manuscript.

**Lemma B.1** If $X \in \mathbb{R}^{n \times p_1}$ is a zero mean subgaussian matrix with parameters $(\Sigma_x, \sigma_x^2)$, then for any fixed (unit) vector in $v \in \mathbb{R}^{p_1}$, we have

\[(i) \quad P\left(\|Xv\|_2^2 - E\|Xv\|_2^2 \geq nt\right) \leq \exp \left(-cn \min\left\{\frac{t^2}{\sigma_x^2}, \frac{t}{\sigma_x^2} \right\}\right)\]

Moreover, if $Y \in \mathbb{R}^{n \times p_2}$ is a zero mean subgaussian matrix with parameters $(\Sigma_y, \sigma_y^2)$, then

\[(ii) \quad P\left(\|Y^T X\|_n - \text{cov}(y_i, x_i)\|_\infty \geq t\right) \leq 6p_1p_2 \exp \left(-cn \min\left\{\frac{t^2}{\sigma_x^2 \sigma_y^2}, \frac{t}{\sigma_x \sigma_y} \right\}\right)\]

where $x_i, y_i$ are the $i^{th}$ rows of $X$ and $Y$ respectively. In particular, if $n \geq c\log p$, then

\[(iii) \quad P\left(\|Y^T X\|_n - \text{cov}(y_i, x_i)\|_\infty \geq c \sigma_x \sigma_y \sqrt{\frac{\log p}{n}}\right) \leq c_1 \exp(-c_2 \log p)\]

This lemma provides tail bounds on subexponential r.v.’s and is as stated in Lemma 14 of Loh and Wainwright (2012): supplementary materials. The first part of this lemma is a restatement of Proposition 5.16 of Vershynin (2010) and the other two part are derived via algebraic manipulations of the product under consideration. The following is another useful result from Loh and Wainwright (2012) which provides control on restricted eigenvalues of the gram matrix.

**Lemma B.2** Let $z_i \in \mathbb{R}^p$, $i = 1, \ldots, n$ be i.i.d subgaussian random vectors with variance parameter $\sigma_z^2$ and covariance $\Sigma_z = E z_i z_i^T$. Also, let $\lambda_{\min}(\Sigma_z)$ and $\lambda_{\max}(\Sigma_z)$ be the minimum
and maximum eigenvalues of the covariance matrix respectively. Then,

\[(i) \quad \frac{1}{n} \sum_{i=1}^{n} \delta^T z_i z_i^T \delta \geq \frac{\lambda_{\min}(\Sigma_z)}{2} \|\delta\|_2^2 - c_u \lambda_{\min}(\Sigma_z) \max \left\{ \frac{\sigma_z^4}{\lambda_{\min}(\Sigma_z)}, 1 \right\} \frac{\log p}{n} \|\delta\|_2^2, \quad \forall \delta \in \mathbb{R}^p,\]

\[(ii) \quad \frac{1}{n} \sum_{i=1}^{n} \delta^T z_i z_i^T \delta \leq \frac{3\lambda_{\max}(\Sigma_z)}{2} \|\delta\|_2^2 + c_u \lambda_{\min}(\Sigma_z) \max \left\{ \frac{\sigma_z^4}{\lambda_{\min}(\Sigma_z)}, 1 \right\} \frac{\log p}{n} \|\delta\|_2^2, \quad \forall \delta \in \mathbb{R}^p,\]

with probability at least \(1 - c_1 \exp(-c_2 \log p)\).

A proof of this result in an errors-in-variables setting result can be found in the supplementary material of Loh and Wainwright (2012), However Lemma B.2 can be seen to follow as a special case (substitute \(\sigma_w = 0\) in Lemma 1 of Loh and Wainwright (2012): supplementary materials).

**Lemma B.3** Let the \(\{X_i\}_{i=1}^{m}\) be independent random variables, \(EX_i^2 < \infty, X_i \geq 0\). Set \(S = \sum_{i=1}^{n} X_i\) and let \(t > 0\). Then

\[
P(ES - S \geq t) \leq \exp \left( \frac{-t^2}{2 \sum_{i=1}^{n} EX_i^2} \right)
\]

This result is as stated in Theorem 1 of Maurer (2003), it provides a lower bound on a sum of positive independent r.v.'s.

**Lemma B.4** Suppose \(X\) and \(Y\) are independent random variables. Let \(\phi\) be a function with \(E|\phi(X, Y)| < \infty\) and let \(g(x) = E\phi(x, Y)\), then

\[
E(\phi(X, Y)|X) = g(X)
\]

This is an elementary result on conditional expectations. A straightforward proof can be found in Example 1.5. page 222, Durrett (2010).
